Fast Robust Matrix Completion via Entry-Wise \(\ell_0\)-norm Minimization

Xiao Peng Li, Zhang-Lei Shi, Qi Liu, Hing Cheung So, Fellow, IEEE

Abstract

Matrix completion (MC) aims at recovering missing entries given an incomplete matrix. Existing algorithms for MC are mainly designed for noiseless or Gaussian noise scenarios and thus they are not robust to impulsive noise. For outlier resistance, entry-wise \(\ell_p\)-norm with \(0 < p < 2\) and M-estimation are two popular approaches. Yet the optimum selection of \(p\) for the entry-wise \(\ell_p\)-norm based methods is still an open problem. Besides, M-estimation is limited by a breakdown point, that is, the largest proportion of outliers. In this paper, we adopt entry-wise \(\ell_0\)-norm, namely, the number of nonzero entries in a matrix, to separate anomalies from the observed matrix. Prior to separation, Laplacian kernel is exploited for outlier detection, which provides a strategy to automatically update the entry-wise \(\ell_0\)-norm penalty parameter. The resultant multi-variable optimization problem is addressed by block coordinate descent (BCD), yielding \(\ell_0\)-BCD and \(\ell_0\)-BCD-F. The former detects and separates outliers, as well as its convergence is guaranteed. In contrast, the latter attempts to treat outlier-contaminated elements as missing entries, which leads to higher computational efficiency. Making use of majorization-minimization (MM), we further propose \(\ell_0\)-BCD-MM and \(\ell_0\)-BCD-MM-F for robust nonnegative MC where the nonnegativity constraint is handled by a closed-form update. Experimental results of image inpainting and hyperspectral image recovery demonstrate that the suggested algorithms outperform several state-of-the-art methods in terms of recovery accuracy and computational efficiency.

Index Terms

Matrix completion, nonnegative matrix completion, robust recovery, outlier detection, \(\ell_0\)-norm optimization.

I. Introduction

Matrix completion (MC) refers to restoring the missing entries of an incomplete matrix by making use of the low-rank property, and has various applications, including machine learning [1], system identification [2], computer vision [3], image inpainting [4], and target estimation [5]. This is because many real-world signals can be represented/approximated as low-rank matrices. For instance, image data can be modeled as low-rank matrices since the main information is dominated by the largest singular values, associating with their left and right singular vectors [6].

Mathematically, MC is formulated as a constrained rank minimization problem [7]. Unfortunately, it is NP-hard as the rank function is both nonconvex and discrete. The nuclear norm has been proved to be a convex envelop of the rank function [8] and hence can be used as its substitute. MC based on the nuclear norm has been handled by singular value thresholding (SVT) [9], fixed point continuation (FPC) [10], accelerated proximal gradient (APG) [11] and truncated nuclear norm regularization (TNNR) [12]. As singular value decomposition (SVD) is required, the aforementioned methods are computationally demanding, especially for large-size matrices.

On the other hand, the nuclear norm, which is equal to the sum of all singular values, may cause the solution to deviate seriously from the ground truth because of its slack relaxation. To handle this issue, weighted nuclear norm method (WNNM) [13] assigns different weights to the singular values. Besides, the capped trace norm and Schatten $p$-norm are suggested to approximate the rank function [14], [15], [16]. Although these two norms have a better rank function approximation, they also require SVD computation. Another way to avoid the slack relaxation is to convert the rank minimization into a rank constraint [17] and then use gradient projection to handle the resultant problem. Since only the truncated SVD is involved, its computational complexity is lower than those implementing full SVD.

To avoid SVD computation, matrix factorization scheme has been suggested for MC [18]. The basic idea is to exploit the product of two much smaller matrices to represent the objective matrix under the assumption that the rank of target matrix is known. Low-rank matrix fitting (LMaFit) [19] is first proposed using matrix factorization, but its global convergence cannot be ensured. Subsequently, MC based on low-rank factorization is proved to obtain the globally optimal solution under some mild conditions [20]. Moreover, locally linear approximation (LLA) [21] adopts the local structure of visual data for recovery performance improvement. Recently, the online robust matrix completion (ORMC) method [22] considers the incomplete matrix containing several Gaussian noise-contaminated columns, and adopts $\ell_{2,1}$-norm as the loss function.

The above-mentioned algorithms can work well when the observed matrix is noise-free or corrupted by white Gaussian noise. Although Gaussian distribution is the best approximation to common noise, non-Gaussian distributed noise has occurred in some fields [23]. For instance, images may be corrupted by salt-and-pepper noise, and communication channels may contain impulsive components. To resist outliers, the entry-wise $\ell_p$-norm with $0 < p < 2$ has been adopted as the loss function, resulting in the alternating projection (AP) [24], $\ell_p$ regression ($\ell_p$-reg) [25], and $\ell_p$-norm based matching pursuit ($\ell_p$-MP) [26]. These
approaches demonstrate outstanding performance in the presence of gross errors. However, the entry-wise $\ell_p$-norm has two open problems. The first is how to select the optimum $p$ for the impulsive noise of a certain intensity since the choice of $p$ affects the recovery performance. The second is that the entry-wise $\ell_p$-norm with $0 < p < 1$ is nonsmooth and nonconvex, which poses a challenge for optimization. Besides, the works in [27], [28] suggest adopting the M-estimators to deal with robust matrix completion (RMC). Nevertheless, M-estimation has a breakdown point that depends on the largest proportion of anomalies [29]. Moreover, Bayesian approach has been exploited to solve RMC, which includes the Bayesian estimator for noisy MC (BENMC) [30] and variational Bayesian matrix factorization based on $\ell_1$-norm (VBMFL1) [31]. Recently, the correntropy-induced loss function and $\ell_1$-norm formulated as a regularization term are applied for RMC [32], [33].

In applications such as blind recommender systems [34], sensor calibration [35], and hyperspectral imaging [36], [37], data are nonnegative. However, MC methods may result in negative entries in the recovered matrix, which violates the inherent data property. To handle this issue, nonnegative matrix completion (NMC) approaches are proposed, including matrix factorization with alternating direction method of multipliers (MF-ADMM) [38], low-rank approximation with ADMM (LRA-ADMM) [39], and NMC using Nesterov iterations (NeNMC) [40]. Compared with MC, NMC ensures that all entries of the recovered matrix are nonnegative. However, most existing NMC algorithms are not robust to outliers.

In this paper, we exploit the entry-wise $\ell_0$-norm, which is equal to the number of nonzero entries, to separate anomalies from the observed matrix. In addition, we combine the entry-wise $\ell_0$-norm with the matrix factorization strategy to formulate the RMC problem. Then, block coordinate descent (BCD) [41] is adopted as the solver for the resultant multi-variable optimization problem. The developed algorithms, called $\ell_0$-BCD and $\ell_0$-BCD-F, update one block with fixing the remaining blocks at each iteration. The former detects and separates outliers from the noisy matrix, while the latter considers the outlier-contaminated elements as missing entries. Therefore, the $\ell_0$-BCD-F has lower computational complexity than the $\ell_0$-BCD. To detect outliers, Laplacian kernel is exploited, resulting in an adaptive method to update the penalty parameter of the $\ell_0$-norm. On the other hand, the above scheme is applied to deal with robust NMC (RNMC), yielding two algorithms, namely, $\ell_0$-BCD-MM and $\ell_0$-BCD-MM-F. They use majorization-minimization (MM) to handle the least squares problem with nonnegativity constraint. Unlike the projected gradient descent whose convergence depends on an appropriate choice of step-size, the $\ell_0$-BCD-MM and $\ell_0$-BCD-MM-F provide a closed-form update without this parameter. Our main contributions are summarized as:

(i) The entry-wise $\ell_0$-norm is formulated as a penalty term to separate anomalies. In addition, the Laplacian kernel function is exploited to devise an outlier detector for identifying anomalies, by which the penalty parameter of the $\ell_0$-norm is automatically updated. The proposed algorithms achieve a higher recovery accuracy than existing approaches for synthetic and real-world data in the presence of outliers.

(ii) A novel perspective is suggested to address RMC, i.e., outlier-contaminated entries are considered as missing elements. This reduces the algorithm computational requirement, resulting in a faster variant,
namely, $\ell_0$-BCD-F. Its computational efficiency is much higher than the existing techniques.

(iii) To tackle the nonnegative least squares problem in RNMC, we adopt MM to develop a closed-form update which is proved to meet the Karush-Kuhn-Tucker (KKT) conditions. Compared with the projected gradient descent that requires an appropriate value of step-size [42], our algorithm is parameter-free.

The remainder of this paper is organized as follows. In Section II, we introduce notations and preliminaries, including problem formulation and representative solvers. Two efficient algorithms for RMC, i.e., $\ell_0$-BCD and $\ell_0$-BCD-F, are developed in Section III. In Section IV, we propose $\ell_0$-BCD-MM and $\ell_0$-BCD-MM-F to tackle RNMC. Numerical results based on synthetic and real-world data are presented in Section V. Finally, Section VI provides concluding remarks.

II. Overview of Related Work

A. Notations

Scalars, vectors, and matrices are represented by italic, bold lower-case, and bold upper-case letters, respectively. Besides, a matrix of ones is signified by $\mathbf{1}$. For matrices, $\| \cdot \|_*$ is the nuclear norm while $\| A \|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n a_{i,j}^2}$ is the Frobenius norm where $a_{i,j}$ is the $(i,j)$ entry of $A \in \mathbb{R}^{m \times n}$. The $\| A \|_p$ with $0 < p < 2$ is calculated using the sum of $p$ power of all elements. The element-wise absolute operation of $A$ is represented by $| A |$. Moreover, $A \geq 0$ and $A \succeq 0$ signify that $A$ is a nonnegative matrix and positive semidefinite matrix, respectively. Furthermore, $a_i^T$ is the $i$th row of $A$, while $a_j$ is the $j$th column of $A$. For a vector $a \in \mathbb{R}^m$, $\| a \|_2 = \sqrt{\sum_{i=1}^m a_i^2}$ and $\| a \|_1 = \sum_{i=1}^m | a_i |$ are $\ell_2$-norm and $\ell_1$-norm, respectively. In addition, dim($a$) indicates the length of $a$. The entry-wise $\ell_0$-norm for vectors and matrices is denoted by $\| \cdot \|_0$ which is the total number of nonzero entries. The pseudo-inverse and transpose operators are signified by $(\cdot)^+$ and $(\cdot)^T$, respectively.

B. Matrix Completion Formulation

Consider an incomplete matrix $\mathbf{X}_\Omega \in \mathbb{R}^{m \times n}$ where $\Omega \in \mathbb{R}^{m \times n}$ is a binary matrix, consisting of 0 and 1. Here, $\mathbf{X}_\Omega$ denotes that $\mathbf{X}$ projects onto $\Omega$, resulting in

$$(\mathbf{X}_\Omega)_{i,j} = \begin{cases} x_{i,j}, & \text{if } \Omega_{i,j} = 1, \\ 0, & \text{otherwise.} \end{cases}$$

Ideally, the MC problem is formulated as a rank minimization problem [7]:

$$\min_M \text{rank}(M) \text{ s.t. } M = \mathbf{X}_\Omega. \tag{2}$$

It means that MC aims at seeking $M \in \mathbb{R}^{m \times n}$ with minimum rank under the constraint where the entries of the recovered and observed matrices in $\Omega$ are equal. Yet rank minimization is an NP-hard problem. One popular and feasible method is to adopt matrix factorization [19], leading to

$$\min_{U,V} \| (UV)_\Omega - \mathbf{X}_\Omega \|_F^2, \tag{3}$$
where the recovered matrix is represented by the product of two low-dimensional matrices, namely, $U \in \mathbb{R}^{m \times r}$ and $V \in \mathbb{R}^{r \times n}$. Herein, $r$ is the rank of the recovered matrix. Since (3) does not require computing SVD, it has lower computational complexity compared to the nuclear norm based algorithms. However, its performance will be degraded when the observed entries involve gross errors. The reason is that the Frobenius norm amplifies the power of outliers which is much larger than that of the Gaussian noise.

One of the prevailing approaches to resist outliers is to use the entry-wise $\ell_p$-norm with $0 < p < 2$ [25]:

$$\min_{U,V} \| (UV)_{\Omega} - X_{\Omega} \|_p^p.$$  (4)

Consider a residual $e = (UV)_{i,j} - x_{i,j}$ corresponding to an outlier, we get $|e|^p < |e|^2$ with $0 < p < 2$. That is, the entry-wise $\ell_p$-norm is able to weaken the impact of outliers and thus the entry-wise $\ell_p$-norm has better performance than the Frobenius norm in impulsive noise environment.

Another approach for RMC is based on the maximum correntropy criterion [32]:

$$\min_{U,V} \| (UV)_{\Omega} - X_{\Omega} \|_{G_\sigma},$$  (5)

where $\| \cdot \|_{G_\sigma}$ is the correntropy-induced loss function, defined as

$$\| A \|_{G_\sigma} = \sum_{i=1}^{m} \sum_{j=1}^{n} \sigma^2 \left( 1 - \exp \left( -\frac{a_{i,j}^2}{2\sigma^2} \right) \right),$$  (6)

where $\sigma > 0$ is the kernel width. Since solving (5) requires a three-layer iterative procedure, the resultant algorithm has relatively high computational complexity.

In addition, the entry-wise $\ell_0$-norm has been applied for RMC [43], resulting in

$$\min_{M,E} \| M_{\Omega} - X_{\Omega} + E_{\Omega} \|_F^2 + \frac{\alpha}{2} \| M_{\Omega} \|_F^2,$$

s.t. $\| E \|_0 \leq N_0$, $\| E \|_2 \leq K_E$, rank($M$) $\leq r$,  (7)

where $\alpha > 0$ is a penalty parameter, $\Omega$ is a subset of $\Omega$ and does not contain the indices of the outlier-contaminated entries, $N_0$ is a positive integer to limit the number of outliers, and $K_E$ is a finite constant to facilitate the convergence. However, the method to solve (7) is computationally expensive since it requires performing SVD. Besides, the number of anomalies should be estimated in advance, which is a challenge for real-world data.

C. Nonnegative Matrix Completion Formulation

Analogous to MC, NMC can be formulated as [38], [39]:

$$\min_{U,V} \| (UV)_{\Omega} - X_{\Omega} \|_F^2,$$

s.t. $U \geq 0, V \geq 0$,  (8)

where $U \geq 0$ and $V \geq 0$ ensure the recovered matrix nonnegative. In this work, we develop a method to solve the nonnegativity constraint of RNMC. Prior to introducing our idea, two existing approaches are first reviewed. To facilitate presentation, we assume that $\Omega = 1$ in (8). In this way, we can obtain a special case of RNMC, i.e., nonnegative low-rank matrix approximation.
The most famous method for nonnegative matrix factorization is the multiplicative update [44]:

\[ u_{i,j}^{k+1} = u_{i,j}^k \frac{(X_{\Omega}(V^k)^T)_{i,j}}{(U^kV^k(V^k)^T)_{i,j}} , \quad (9a) \]

\[ v_{i,j}^{k+1} = v_{i,j}^k \frac{((U^{k+1})^TX_{\Omega})_{i,j}}{((U^{k+1})^TU^{k+1}V^k)_{i,j}} . \quad (9b) \]

Note that the solution to (9) is \( U > 0 \) and \( V > 0 \) which is not strictly equivalent to \( U \geq 0 \) and \( V \geq 0 \). Moreover, the convergence of the multiplicative update cannot be ensured [45].

Another approach is to exploit projected gradient descent [42], resulting in

\[ U^{k+1} = \max(0, U^k - \eta((U^kV^k)_\Omega - X_{\Omega})(V^k)^T) , \quad (10a) \]

\[ V^{k+1} = \max(0, V^k - \eta(U^{k+1})^T((U^{k+1}V^k)_\Omega - X_{\Omega})) . \quad (10b) \]

where \( \eta > 0 \) is the step-size. Compared with multiplicative update, its convergence is guaranteed. But \( \eta \) should be appropriately chosen to compromise between the convergence speed and accuracy.

### III. Proposed Algorithms for Robust Matrix Completion

In this section, two algorithms are proposed for RMC, including a basic version and its fast variant. Besides, a Laplacian kernel based anomaly detector is developed for adaptively updating the penalty parameter.

#### A. Algorithm Development

We consider that the impulsive noise comprises Gaussian noise with small power and sparse impulses with large power. Hence, \( X_{\Omega} \) that is corrupted by impulse noise is formulated as

\[ X_{\Omega} = \bar{X}_{\Omega} + G_{\Omega} + S_{\Omega} . \quad (11) \]

where \( \bar{X}_{\Omega} \) is the incomplete noise-free matrix, \( G_{\Omega} \) represents the Gaussian noise, and \( S_{\Omega} \) signifies the sparse impulses. Based on matrix factorization, we recast the RMC problem as

\[ \min_{U,V,S} \|X_{\Omega} - (UV)_{\Omega} - S_{\Omega}\|_2^2 + \mu\|S_{\Omega}\|_0 . \quad (12) \]

where \( \|S_{\Omega}\|_0 \) is utilized to separate outliers from \( X_{\Omega} \). \( \|X_{\Omega} - (UV)_{\Omega} - S_{\Omega}\|_2^2 \) is able to resist the Gaussian noise, and \( \mu > 0 \) is the penalty parameter which controls the sparsity of \( S_{\Omega} \). In our algorithms, \( \mu \) is automatically updated by a Laplacian kernel based method.

Before proceeding, we analyze the advantage of (12) over the entry-wise \( \ell_p \)-norm based methods and Huber loss based approaches. It is known that the Frobenius norm is superior to the \( \ell_p \)-norm under Gaussian noise. For impulsive noise, it is generally comprised of normal disturbances and outliers. In comparison with the Frobenius norm, the \( \ell_p \)-norm weakens the impact of outliers, but cannot handle Gaussian noise as good as the Frobenius norm. In (12), the \( \ell_0 \)-norm and Frobenius norm are able to attain optimality to separate the anomalies and resist the Gaussian noise, respectively. Therefore, our formulation may attain better recovery performance than traditional robust models.
It is clear that (12) is an unconstrained and multi-variable optimization problem with three variables, namely, \( U, V \) and \( S \). Therefore, BCD is adopted as the solver, leading to the following iterative procedure:

\[
U^{k+1} = \arg \min_U \|X_\Omega - (UV^k)\Omega - S_\Omega^k\|_F^2, \tag{13a}
\]

\[
V^{k+1} = \arg \min_V \|X_\Omega - (U^{k+1}V)\Omega - S_\Omega^k\|_F^2, \tag{13b}
\]

\[
S^{k+1} = \arg \min_S \|X_\Omega^{k+1} - S_\Omega\|_F^2 + \mu^{k+1}\|S_\Omega\|_0, \tag{13c}
\]

where \( N^{k+1}_\Omega = X_\Omega - (U^{k+1}V^{k+1}\Omega) \). Note that \( \mu \) is updated by Algorithm 2 before computation of \( S^{k+1} \), hence \( \mu^{k+1} \) replaces \( \mu \). It is seen that the BCD alternately optimizes one of the variables with fixing the two remaining variables at each iteration. We first focus on computing \( U^{k+1} \) hence \( S^{k+1} \), where \( \mu \) is rewritten as \( \mu = \frac{\lambda^2}{\|X_\Omega\|_F^2} \).

Specifically, we decompose \( U^{k+1} \) given \( V^k \) and \( S^k \). As (13a) can be decoupled with respect to (w.r.t.) \( u_i^T \), it is equivalent to the following \( m \) independent subproblems

\[
(u_i^T)^{k+1} = \arg \min_{u_i^T} \|(u_i^T V^k)_{\Omega_i} - (y_i^T)_{\Omega_i}\|_2^2, \tag{14}
\]

where \( (y_i^T)_{\Omega_i} \) and \( \Omega_i \) are the \( i \)th row of \( Y_\Omega = X_\Omega - S^k_\Omega \) and \( \Omega \), respectively. It is clear that the residual between \( (u_i^T V^k)_{\Omega_i} \) and \( (y_i^T)_{\Omega_i} \) is only affected by the observed entries. Therefore, we remove the unobserved elements, leading to

\[
(u_i^T)^{k+1} = \arg \min_{u_i^T} \|u_i^T A - b_i\|_2^2, \tag{15}
\]

where \( b_i = \Omega_i \) and \( A \) only contain the observed entries of \( (y_i^T)_{\Omega_i} \) and the corresponding columns of \( V^k \), respectively. To be specific, we provide an example for determining \( A \) and \( b \). Consider \( V^k = [v_1, v_2, v_3, v_4, v_5] \in \mathbb{R}^{r \times 5} \) and \( (y_i^T)_{\Omega_i} = [0, y_2, 0, y_4, 0] \in \mathbb{R}^5 \) with \( \Omega_i = [0, 1, 0, 1, 0] \). Then, we get \( A = [v_2, v_4] \) and \( b = [y_2, y_4] \).

Since (15) is a linear least squares problem, its closed-form solution is

\[
(u_i^T)^{k+1} = b^T(A)^\dagger, \tag{16}
\]

whose computational complexity is \( O(\|\Omega_i\|_2^1 r^2) \).

Problem (13b) has the same structure as (13a) and hence (13b) can be addressed in a similar manner. Specifically, we decompose (13b) into \( n \) independent subproblems:

\[
u_j^{k+1} = \arg \min_{v_j} \|(U^{k+1}v_j)_{\Omega_j} - (y_j)_{\Omega_j}\|_2^2, \tag{17}
\]

where \( (y_j)_{\Omega_j} \) and \( \Omega_j \) are the \( j \)th column of \( Y_\Omega \) and \( \Omega \), respectively. After removing the missing entries, (17) is rewritten as

\[
u_j^{k+1} = \arg \min_{v_j} \|C v_j - d\|_2^2, \tag{18}
\]

where \( d = \Omega_j \) and \( C \) only involve the observed entries of \( (y_j)_{\Omega_j} \) and corresponding rows of \( U^{k+1} \), respectively. Then, the solution to (18) is

\[
u_j^{k+1} = (C^T C)^\dagger d, \tag{19}
\]
Algorithm 1 \( \ell_0 - \text{BCD} \) for RMC

Input: \( \mathbf{X}, \Omega, r \) and \( K_{\text{max}} \)

Initialize: Randomly initialize \( \mathbf{V}^1 \in \mathbb{R}^{r \times n} \), and \( \mathbf{S}^1 = 0 \in \mathbb{R}^{m \times n} \)

for \( k = 1, 2, \cdots, K_{\text{max}} \) do
  for \( i = 1, 2, \cdots, m \) do
    Compute \( (\mathbf{u}_i^T)^{k+1} \) using (15)
  end for
  for \( j = 1, 2, \cdots, n \) do
    Compute \( \mathbf{v}_j^{k+1} \) using (18)
  end for
  Construct \( \mathbf{N}^{k+1}_\Omega = \mathbf{X} - (\mathbf{U}^{k+1}\mathbf{V}^{k+1})\Omega \)
  Compute \( \tilde{\mu}_{k+1} \) with input \( |\mathbf{n}^{k+1}| \) via Algorithm 2
  \( \mu^{k+1} = \min(\tilde{\mu}_{k+1}, \mu^k) \)
  \( \mathbf{s}^{k+1} = T_{\mu^{k+1}}(\mathbf{n}^{k+1}) \)
  Calculate \( \mathbf{S}^{k+1} \) based on \( \mathbf{s}^{k+1} \) and \( \Omega \)
end for

Output: \( \mathbf{M} = \mathbf{U}^{k+1}\mathbf{V}^{k+1} \)

with computational complexity of \( \mathcal{O}(\|\Omega\|_1 r^2) \).

For (13c), its solution is only determined by the observed entries of \( \mathbf{N}^{k+1}_\Omega \). In addition, \( s_{i,j} \) only depends on \( (n^{k+1})_{i,j} \). We then rewrite (13c) in vector form:

\[
\mathbf{s}^{k+1} = \arg \min_{\mathbf{s}} \|\mathbf{n}^{k+1} - \mathbf{s}\|_2^2 + \mu^{k+1}\|\mathbf{s}\|_0, \tag{20}
\]

where \( \mathbf{s} \in \mathbb{R}^{\|\Omega\|_1} \) and \( \mathbf{n}^{k+1} \in \mathbb{R}^{\|\Omega\|_1} \). Note that the method to determine \( \mu^{k+1} \) is presented in the next subsection. The process of attaining \( \mathbf{n}^{k+1} \) from \( \mathbf{N}^{k+1}_\Omega \) is illustrated as follows

\[
\mathbf{N}^{k+1}_\Omega = \begin{bmatrix} 0 & n_{12} & 0 & n_{14} \\ n_{21} & n_{22} & n_{23} & 0 \end{bmatrix}, \tag{21}
\]

and the corresponding \( \Omega \) is \( \Omega = [0, 1, 0, 1; 1, 1, 0] \). Then, we get \( \mathbf{n}^{k+1} = [n_{21}, n_{12}, n_{22}, n_{23}, n_{14}]^T \).

For (20), its solution is computed as

\[
\mathbf{s}^{k+1} = T_{\mu^{k+1}}(\mathbf{n}^{k+1}) = \begin{cases} (n^{k+1})_i, & \text{if } |(n^{k+1})_i| \geq \sqrt{\mu^{k+1}} \\ 0, & \text{otherwise} \end{cases}, \tag{22}
\]

where \( T_{\mu^{k+1}}(\cdot) \) is a hard-thresholding operator that keeps the values above the threshold, and sets the variables below the threshold to 0 [46]. After obtaining \( \mathbf{s}^{k+1} \), we update \( \mathbf{S}^{k+1} \) based on \( \mathbf{s}^{k+1} \) and \( \Omega \) via the inverse operation of getting \( \mathbf{n}^{k+1} \) from \( \mathbf{N}^{k+1}_\Omega \). The proposed method is named \( \ell_0 - \text{BCD} \) whose steps are summarized in Algorithm 1. Furthermore, its convergence analysis is provided in Appendix A.
Algorithm 2 Outlier detector based on Laplacian kernel

Input: \( \mathbf{n} \) and \( \epsilon \)
\[
\sigma^2 = 1.06 \times \min(\sigma_E, IQR/1.34) \times \dim(\mathbf{n})^{-0.2}
\]
\[
\mathbf{w} = k_\sigma(\mathbf{n})
\]
\[
\Psi = \{i\} \text{ based on } w_i \leq \epsilon
\]
\[
\mu = \min(n_1^2, n_2^2, \ldots, n_i^2) \text{ s.t. } i \in \Psi
\]

Output: \( \mu \) and \( \Psi \)

B. Adaptive Penalty

In traditional penalty methods, the penalty parameter \( \mu \) is manually set and fixed during iterations. It is known that if \( \mu \) is chosen too large or too small, the results may be considerably different. Therefore, a dynamical and adaptive \( \mu \) may be preferred in real-world applications.

It can be known from (22) that \( \mu \) in \( \ell_0 \)-BCD determines the sparsity of \( \mathbf{S}_\Omega \), that is, the number of outliers. Hence, the core of estimating \( \mu \) is how to identify anomalies accurately from the residual. Laplacian kernel \([47]\) is one popular method to detect outliers, defined as
\[
k_\sigma(x - y) = \exp \left( -\frac{|x - y|}{\sigma} \right),
\]
Note that \( \sigma \) is termed as kernel size or bandwidth. It is determined using the concept of kernel density estimation, namely, Silverman’s rule \([48]\). The value of \( k_\sigma(x - y) \) decreases as the value of \( |x - y| \) increases. Especially, the very large value of \( |x - y| \) results in \( k_\sigma(x - y) = 0 \). Hence, the Laplacian kernel has outlier detection capability \([49]\).

To estimate \( \mu \) given an input \( \mathbf{n} \), we first adopt the Silverman’s rule to compute the kernel size:
\[
\sigma = 1.06 \times \min(\sigma_E, IQR/1.34) \times \dim(\mathbf{n})^{-0.2},
\]
where \( \sigma_E \) and \( IQR \) are the standard deviation and interquartile range of \( \mathbf{n} \), respectively. After obtaining \( \sigma \), we compute \( \mathbf{w} \) as \( \mathbf{w} = k_\sigma(\mathbf{n}) \) where \( w_i \leq \epsilon \) means that \( n_i \) is an outlier. In our method, \( \epsilon \) is set to \( 10^{-20} \). Based on \( \mathbf{w} \), we get a coordinate set \( \Psi \) of anomalies for \( w_i \leq \epsilon \) and then \( \mu \) is calculated as
\[
\mu = \min(n_1^2, n_2^2, \ldots, n_i^2) \text{ s.t. } i \in \Psi.
\]

Estimation of \( \mu \) based on the Laplacian kernel is summarized in Algorithm 2. Give \( \mathbf{n} \in \mathbb{R}^{\|\Omega\|_1} \), the computational complexity for calculating \( \mu \) is \( \mathcal{O}(\|\Omega\|_1) \).

C. Fast Variant

In \( \ell_0 \)-BCD, we retain the indices of the anomalies in \( \Omega \). A novel perspective on solving RMC is that outlier-contaminated elements are treated as missing entries. In accordance with this scheme, we divide \( \Omega \) into two binary matrices such that \( \Omega = \Omega^o + \Omega^g \). That is, 1 in \( \Omega^o \) and \( \Omega^g \) denotes an observed entry
with and without outlier, respectively. In other words, $\Omega^g$ implies that the observed entries are noise-free or corrupted by Gaussian noise. The computational complexities of calculating $(u_T^g)^{k+1}$ and $v_j^{k+1}$ are $O(||\Omega^g_T||_1 r^2)$ and $O(||\Omega_j||_1 r^2)$, respectively. Simply speaking, the computational cost depends on the number of nonzero entries in $\Omega$. If $\Omega^g$ replaces $\Omega$ to handle MC problem, the computational complexity will reduce because $||\Omega^g||_1 \leq ||\Omega||_1$.

Based on the above-mentioned idea, the iterative procedure to solve (12) is rewritten as

$$U^{k+1} = \arg\min_{U} \|X_{\Omega^{g,k}} - (UV^k)_{\Omega^{g,k}} - S_{\Omega^{g,k}}^k\|_F^2,$$  

(26a)

$$V^{k+1} = \arg\min_{V} \|X_{\Omega^{g,k}} - (U^{k+1}V)_{\Omega^{g,k}} - S_{\Omega^{g,k}}^k\|_F^2,$$  

(26b)

$$S^{k+1} = \arg\min_{S} \|N^{k+1}_{\Omega} - S_{\Omega}\|_F^2 + \mu^{k+1}\|S_{\Omega}\|_0.$$  

(26c)

Note that the observation set in updating $U^{k+1}$ and $V^{k+1}$ becomes $\Omega^{g,k}$. However, updating $S^{k+1}$ is still based on $\Omega$ since one-off anomaly detection may not be accurate. Computation of $S^{k+1}$ founded on $\Omega$ is able to release the mistaken entries to $\Omega$. The process of solving (26a), (26b), and (26c) is similar to that of $\ell_0$-BCD. Accordingly, $U^{k+1}$, $V^{k+1}$ and $S^{k+1}$ are determined analogous to the $\ell_0$-BCD. The difference is that the fast method requires computing $\Omega^{g,k}$ before updating $U^{k+1}$.

To determine $\Omega^{g,k}$, we first compute a binary $\Omega^{g,k} \in \mathbb{R}^{m \times n}$ based on $S^k$:

$$(\Omega^{g,k})_{i,j} = \begin{cases} 
1, & \text{if } (S^k)_{i,j} \neq 1, \\
0, & \text{otherwise}.
\end{cases}$$  

(27)

Then, $\Omega^{g,k} = \Omega - \Omega^{n,k}$.

Since $S^k$ is updated iteratively by $\ell_0$-BCD, the anomaly impact on computation of $U^k$ and $V^k$ slowly diminishes as iteration increases. In contrast, this fast variant assumes that the entries containing outliers are unobserved. In other words, updating $U^k$ and $V^k$ is not affected by anomalies at the beginning. Compared with the solution which is affected by outliers, the result without the impact of outliers has a smaller estimation error at the same number of iterations. In addition, the fast variant has lower computational complexity than the $\ell_0$-BCD and thus it is termed as $\ell_0$-BCD-F. The steps of the $\ell_0$-BCD-F are summarized in Algorithm 3.

Note that (26a)-(26c) cannot be considered to address the original problem (12) since the solutions of $U$ and $V$ are computed based on a subset of $\Omega$. Thereby, it is difficult to prove its convergence. Its convergence is verified using empirical results in Section V.

D. Computational Complexity Analysis

The computational complexities of calculating $(u_T^g)^k$ and $v_j^k$ are $O(||\Omega^g_T||_1 r^2)$ and $O(||\Omega_j||_1 r^2)$, respectively. Besides, calculating $\mu^k$ requires the complexity of $O(||\Omega||_1)$. Since $\sum_{i=1}^m ||\Omega_T^i||_1 = \sum_{j=1}^n ||\Omega_j||_1 = ||\Omega||_1$, $\ell_0$-BCD has the computational complexity of $O(||\Omega||_1 r^2)$ for one iteration.
Algorithm 3 $\ell_0$-BCD-F for RMC

Input: $X_{\Omega}$, $\Omega$, $r$ and $K_{\text{max}}$

Initialize: Randomly initialize $V^1 \in \mathbb{R}^{r \times n}$, and $S^1 = 0 \in \mathbb{R}^{m \times n}$

for $k = 1, 2, \cdots, K_{\text{max}}$ do

Calculate $\Omega^{o,k}$ via (27)

Update $\Omega^{g,k} = \Omega - \Omega^{o,k}$

Compute $U^{k+1}$ and $V^{k+1}$ based on $\Omega^{g,k}$ using Algorithm 1

Compute $S^{k+1}$ based on $\Omega$ using Algorithm 1

end for

Output: $M = U^{k+1}V^{k+1}$

For $\ell_0$-BCD-F, the outlier-contaminated elements are considered as missing entries and hence we have $\|\Omega^g\|_1 < \|\Omega\|_1$. Besides, the $\ell_0$-BCD-F’s complexity is dominated by the computations of $U^k$ and $V^k$. Accordingly, its complexity is $O(\|\Omega^g\|_1 r^2)$.

Table I: Complexity comparison of different algorithms

<table>
<thead>
<tr>
<th>Method</th>

</tbody>
</table>

Table I tabulates the computational requirement of six algorithms where $T > 0$ is the number of inner iterations in the $\ell_p$-reg, $\ell_p$-ADMM and M-estimation. For VBMFL1, $mn > \|\Omega\|_1$ holds. It is clear that the proposed methods have lower computational complexity than the existing algorithms.

IV. Extension to Nonnegative Matrix Completion

In this section, we extend the ideas in RMC to NRMC, yielding a basic method and its fast variant.

A. Algorithm Development

By modifying RMC, the RNMC formulation is:

$$\min_{U \geq 0, V \geq 0, S} \|X_{\Omega} - (UV)_{\Omega} - S_{\Omega}\|_F^2 + \mu \|S_{\Omega}\|_0,$$

(28)
where \( S \) is not constrained to be positive. Although (28) is a constrained and multi-variable problem, the constraints can be affiliated with each block. Thereby, BCD can also be adopted as the solver, leading to

\[
U^{k+1} = \arg \min_{U \geq 0} \| X_{\Omega} - (UV^k)_{\Omega} - S^k_{\Omega} \|_F^2, \tag{29a}
\]

\[
V^{k+1} = \arg \min_{V \geq 0} \| X_{\Omega} - (U^{k+1}V)_{\Omega} - S^k_{\Omega} \|_F^2, \tag{29b}
\]

\[
S^{k+1} = \arg \min_S \| N^{k+1}_{\Omega} - S_{\Omega} \|_F^2 + \mu^{k+1} \| S_{\Omega} \|_0. \tag{29c}
\]

It is worth mentioning that (13c) and (29c) are the same. To handle (29a) and (29b), the MM algorithm is exploited. We briefly introduce MM for completeness.

B. Majorization-Minimization

Consider a general optimization problem

\[
\min_x h(x) \text{ s.t. } x \in \mathcal{X}, \tag{30}
\]

where \( h : \mathcal{X} \to \mathbb{R} \) is a continuous function and \( \mathcal{X} \) is a nonempty closed set. MM [50], [51] employs a surrogate function \( g(x|x^t) \) of \( h(x) \) to solve the original problem iteratively. Note that \( g(x|x^t) \) should satisfy the following properties:

(i) \( h(x^t) = g(x^t|x^t) \).

(ii) \( h(x) \leq g(x|x^t) \), s.t. \( x \in \mathcal{X} \).

(iii) \( \nabla h(x^t) = \nabla g(x^t|x^t) \).

Then, \( x \) is iteratively updated as

\[
x^{t+1} = \arg \min_x g(x|x^t). \tag{31}
\]

We see that MM uses \( g(x|x^t) \) to approximate the original function at \( x^t \) and then searches for the solution to \( g(x|x^t) \). In addition, the convergence of MM has been proved [51].

C. \( \ell_0 \)-BCD-MM

We first focus on tackling (29a). From \( \ell_0 \)-BCD, it is known that (29a) can be decomposed into \( m \) independent subproblems

\[
(u^T)^{k+1}_i = \arg \min_{u^T_i \geq 0} \| u^T_i A - b^T \|_2^2 = \arg \min_{u^T_i \geq 0} \| A^T u_i - b \|_2^2
\]

\[
= \arg \min_{u_i \geq 0} u_i^T A A^T u_i - 2(Ab)^T u_i + b^T b
\]

\[
= \arg \min_{u_i \geq 0} u_i^T L u_i - 2(Ab)^T u_i, \tag{32}
\]

where \( b^T b \) is dropped since it is a constant w.r.t. \( u_i \), and \( L = A A^T \in \mathbb{R}^{r \times r} \). In order to derive a closed-form update to solve (32), we introduce a surrogate function to majorize the quadratic term of \( u_i^T L u_i \).

Lemma 1 [52]: Let \( L \in \mathbb{R}^{r \times r} \) and \( Q \in \mathbb{R}^{r \times r} \) be real symmetric matrices such that \( Q \succeq L \). Then, for any vector \( u \in \mathbb{R}^r \), the quadratic function \( u^T L u \) is majorized at \( u^t \) by \( u^T Q u + 2u^T (L - Q) u^t + (u^t)^T (Q - L) u^t \).
Based on Lemma 1, the surrogate function of \( u_i^T L u_i \) is formulated as
\[
    u_i^T Q u_i + 2u_i^T (L - Q) u_i + (u_i^T)^T (Q - L) u_i.\tag{33}
\]
To meet \( Q \succeq L \), we set \( Q = \lambda_{\text{max}} I \) where \( \lambda_{\text{max}} \) is the largest eigenvalue of \( L \). Then, we have
\[
    u_i^T L u_i \leq u_i^T Q u_i + 2u_i^T (L - Q) u_i + (u_i^T)^T (Q - L) u_i
    = \lambda_{\text{max}} u_i^T u_i + 2u_i^T (L - \lambda_{\text{max}} I) u_i + (u_i^T)^T (Q - L) u_i
    = \lambda_{\text{max}} u_i^T u_i + 2 ((L - \lambda_{\text{max}} I) u_i)^T u_i + (u_i^T)^T (Q - L) u_i,\tag{34}
\]
where the superscript \( t \) of \( u_i^t \) is the iteration number of the MM method. Hence, the surrogate function \( g(u_i | u_i^t) \) of \( u_i^T L u_i - 2(\beta - \lambda) u_i \) in (32) becomes
\[
    g(u_i | u_i^t) = \lambda_{\text{max}} u_i^T u_i + 2 ((L - \lambda_{\text{max}} I) u_i - \beta u_i)^T u_i
    + (u_i^T)^T (Q - L) u_i.\tag{35}
\]
Then, according to MM, we iteratively update \( g(u | u^t) \) to solve (32) by
\[
    u_i^{t+1} = \arg \min_{u_i \geq 0} g(u_i | u_i^t)
    = \arg \min_{u_i \geq 0} u_i^T u_i + (q^t)^T u_i,\tag{36}
\]
where the term \( (u_i^T)^T (Q - L) u_i \) is dropped as it is a constant w.r.t. \( u_i \), and \( (q^t)^T = \frac{2}{\lambda_{\text{max}}} ((L - \lambda_{\text{max}} I) u_i^t - \beta u_i)^T \).

The closed-form solution to (36) is
\[
    u_i^{t+1} = \mathcal{I}(q^t) = \begin{cases} 
        \frac{q_i^t}{2}, & \text{if } q_i^t < 0, \\
        0, & \text{otherwise}. 
    \end{cases} \tag{37}
\]
The proof of the closed-form solution is provided in Appendix B. When \( u_i^{t+1} \) converges, it becomes the optimal solution to (32).

For (29b), it can be handled in a similar way, leading to the following \( n \) independent subproblems:
\[
    \mathbf{v}_j^{k+1} = \arg \min_{\mathbf{v}_j \geq 0} \| C \mathbf{v}_j - \mathbf{d} \|^2_2
    = \arg \min_{\mathbf{v}_j \geq 0} \mathbf{v}_j^T C^T C \mathbf{v}_j - 2 \mathbf{C}^T \mathbf{d} \mathbf{v}_j + \mathbf{d}^T \mathbf{d}
    = \arg \min_{\mathbf{v}_j \geq 0} \mathbf{v}_j^T L \mathbf{v}_j - 2 \mathbf{C}^T \mathbf{d} \mathbf{v}_j,\tag{38}
\]
where \( L = \mathbf{C}^T \mathbf{C} \). It is clear that (38) is equivalent to (32). Thus, \( \mathbf{v}_j^{k+1} \) can be sought via the same way
\[
    \mathbf{v}_j^{t+1} = \arg \min_{\mathbf{v}_j \geq 0} \mathbf{v}_j^T \mathbf{v}_j + (q^t)^T \mathbf{v}_j,\tag{39}
\]
where \( (q^t)^T = \frac{2}{\lambda_{\text{max}}} ((L - \lambda_{\text{max}} I) \mathbf{v}_j^t - \mathbf{C}^T \mathbf{d})^T \). When \( \mathbf{v}_j^{t+1} \) converges, \( \mathbf{v}_j^{k+1} \) is determined, that is, \( \mathbf{v}_j^{k+1} = \mathbf{v}_j^{t+1} \).

Finally, (29c) is the same as (13c) in the \( \ell_0 \)-BCD and hence \( S^{k+1} \) can be computed as in Algorithm 1.

Algorithm 4 summarizes the steps of \( \ell_0 \)-BCD-MM. Note that there are three layers of iterative updates. The outer updates on \( \mathbf{U}^{k+1} \), \( \mathbf{V}^{k+1} \), and \( S^{k+1} \) correspond to the BCD method. The middle layer calculates \( u_i^{k+1} \) and \( \mathbf{v}_j^{k+1} \) of \( \mathbf{U}^{k+1} \) and \( \mathbf{V}^{k+1} \), respectively. The inner refers to the iteration of the MM algorithm. Parallel and
Algorithm 4 $\ell_0$-BCD-MM for RNMC

Input: $X_{\Omega}, \Omega, r$ and $K_{\text{max}}$

Initialize: Randomly initialize $V^1 \in \mathbb{R}^{r \times n}$, and $S^1 = 0 \in \mathbb{R}^{m \times n}$

for $k = 1, 2, \ldots, K_{\text{max}}$ do

for $i = 1, 2, \ldots, m$ do

Randomly initialize $u_i^0 \in \mathbb{R}^r$

Compute $\lambda_{\text{max}}$ based on $L = AA^T$

for $t = 1, 2, \ldots$ do

$q^t = \frac{2}{\lambda_{\text{max}}}((L - \lambda_{\text{max}}I)u_i^t - Ab)$

$u_i^{t+1} = \mathcal{I}(q^t)$

Stop if stopping criterion is met.

end for

$u_i^{k+1} = u_i^{t+1}$

end for

for $j = 1, 2, \ldots, n$ do

Randomly initialize $v_j^0 \in \mathbb{R}^r$

Compute $\lambda_{\text{max}}$ based on $L = C^TC$

for $t = 1, 2, \ldots$ do

$q^t = \frac{2}{\lambda_{\text{max}}}((L - \lambda_{\text{max}}I)v_j^t - C^Td)$

$v_j^{t+1} = \mathcal{I}(q^t)$

Stop if stopping criterion is met.

end for

$v_j^{k+1} = v_j^{t+1}$

end for

Construct $N_{\Omega}^{k+1} = X_{\Omega} - (U^{k+1}V^{k+1})\Omega$

Compute $\mu_{k+1}$ with input $|n^{k+1}|$ via Algorithm 2

Update $\mu^{k+1} = \min(\mu_{k+1}, \mu^k)$

Compute $s^{k+1} = T_{\mu^{k+1}}(n^{k+1})$

Update $S^{k+1}$ based on $s^{k+1}$ and $\Omega$

end for

Output: $M = U^{k+1}V^{k+1}$

distributed computing can be used to calculate $u_i^{k+1}$ and $v_j^{k+1}$ and thus the computational efficiency can be greatly increased. Moreover, the termination condition for $u_i^{t+1}$ is suggested as $\|u_i^{t+1} - u_i^t\|^2 / \text{dim}(u) < 10^{-5}$ which means that the average power difference between adjacent iterations of each entry is less than $10^{-5}$. Similarly, $v_j^{t+1}$ also adopts this stopping criterion.
Algorithm 5 \( \ell_0 \)-BCD-MM-F for RNMC

Input: \( X, \Omega, n, r \) and \( K_{\text{max}} \)

Initialize: Randomly initialize \( V^1 \in \mathbb{R}^{r \times n} \), and \( S^1 = 0 \in \mathbb{R}^{m \times n} \).

for \( k = 1, 2, \cdots, K_{\text{max}} \) do

Calculate \( \Omega^{o,k} \) via (27)

Update \( \Omega^{g,k} = \Omega - \Omega^{o,k} \)

Compute \( U^{k+1} \) and \( V^{k+1} \) based on \( \Omega^{g,k} \) using Algorithm 4

Compute \( S^{k+1} \) based on \( \Omega \) using Algorithm 4

end for

Output: \( M = U^{k+1}V^{k+1} \)

Regarding its objective value convergence, the proof of \( \ell_0 \)-BCD is applicable. Since the convergence of MM algorithm is ensured [51], \( u_{i}^{k+1} \) and \( v_{j}^{k+1} \) are the optimal solutions to the convex problems (32) and (38), respectively. That is, the updates of \( U^{k+1} \) and \( V^{k+1} \) by Algorithm 4 keep the objective value nonincreasing. Thus, in accordance to the convergence analysis of the \( \ell_0 \)-BCD, the \( \ell_0 \)-BCD-MM’s convergence is guaranteed.

D. Fast Variant

The strategy in \( \ell_0 \)-BCD-F can be used to speed up the \( \ell_0 \)-BCD-MM. When we treat the outlier-contaminated elements as unobserved entries, the \( \ell_0 \)-BCD-MM evolves into \( \ell_0 \)-BCD-MM-F. The steps of the \( \ell_0 \)-BCD-MM-F are summarized in Algorithm 5.

E. Computational Complexity Analysis

To facilitate presentation, we assume that \( \| \Omega_{T}^{T} \|_1 > \| \Omega_{i} \|_1 \). For \( \ell_0 \)-BCD-MM, the computational complexity for \( L \) is \( \mathcal{O}(r^2 \| \Omega_{T}^{T} \|_1) \). To compute \( \lambda_{\text{max}} \), the complexity is \( \mathcal{O}(r^3) \). The MM computational complexity is \( \mathcal{O}(rT \| \Omega_{T}^{T} \|_1) \) where \( T \) is the required iteration number. Thus, the total computational complexity is \( \mathcal{O}(rT \| \Omega_{T}^{T} \|_1) \) because \( T \gg r \) and \( \sum_{i=1}^{m} \| \Omega_{T}^{T} \|_1 = \| \Omega \|_1 \). On the other hand, the computational complexity of \( \ell_0 \)-BCD-MM-F is \( \mathcal{O}(rT \| \Omega_{g}^{g} \|_1) \).

V. Simulation Results

In this section, the proposed methods are evaluated using synthetic and real-world data. In detail, subsections I and II examine our RMC algorithms, while the remaining two subsections test the suggested NRMC approaches.

A. Synthetic data

The noise-free and complete matrix \( X \in \mathbb{R}^{400 \times 500} \) with \( r = 10 \) is generated by the product of \( X_1 \in \mathbb{R}^{400 \times 10} \) and \( X_2 \in \mathbb{R}^{10 \times 500} \) whose entries obey the standard Gaussian distribution. Then, the incomplete matrix
without noise \( \mathbf{X}_\Omega \) consists of randomly selected 50\% entries from \( \mathbf{X} \). In other words, 50\% entries of \( \Omega \) are equal to 1, and the rest are 0. Moreover, \( \mathbf{X}_\Omega \) is added with independent impulsive noise which is modeled by Gaussian mixture model (GMM). The probability density function (PDF) of GMM is given by

\[
p_r(v) = \frac{c_1}{\sqrt{2\pi\sigma_1}} \exp\left(-\frac{v^2}{2\sigma_1^2}\right) + \frac{c_2}{\sqrt{2\pi\sigma_2}} \exp\left(-\frac{v^2}{2\sigma_2^2}\right),
\]

where \( c_1 + c_2 = 1 \) with \( 0 < c_i < 1 \), \( \sigma_1^2 \) and \( \sigma_2^2 \) are variances. To simulate the impulsive noise, it requires \( \sigma_2^2 \gg \sigma_1^2 \) and \( c_2 < c_1 \). It means that sparse and high power noise samples with \( \sigma_2^2 \) and \( c_2 \) are mixed in Gaussian background noise with small variance \( \sigma_1^2 \). In our simulations, we set \( \sigma_2^2 = 100\sigma_1^2 \) and \( c_2 = 0.1 \). The signal-to-noise ratio (SNR) is defined as

\[
\text{SNR} = \frac{\|\mathbf{X}_\Omega\|_F^2}{\|\Omega\|_1\sigma_2^2},
\]

where \( \sigma_2^2 = \sum_{i=1}^2 c_i\sigma_i^2 \) is the total noise variance.

The recovery performance is measured by mean square error (MSE), defined as

\[
\text{MSE} = \frac{\|\mathbf{M} - \mathbf{X}\|_F^2}{mn},
\]

where \( \mathbf{M} \) is the recovered matrix.

1) Convergence Behavior: We first present the convergence behaviors of the \( \ell_0 \)-BCD and \( \ell_0 \)-BCD-F. Fig. (S.1) in the supplementary material plots the objective value convergence where “Loss” denotes the value of

\[
\mathcal{L}_{\mu^k}(\mathbf{U}^k, \mathbf{V}^k, \mathbf{S}^k) = \|\mathbf{X}_\Omega - (\mathbf{U}^k\mathbf{V}^k)_{\Omega} - \mathbf{S}^k_{\Omega}\|_F^2 + \mu^k\|\mathbf{S}^k_{\Omega}\|_0.
\]

It is seen that the objective value of the proposed algorithms is nonincreasing, and converges within 10 iterations.

Besides, Figs. (S.2) and (S.3) show the sequence convergence of the \( \ell_0 \)-BCD and \( \ell_0 \)-BCD-F, respectively. Since there are numerous entries of \( \mathbf{U}^k \), \( \mathbf{V}^k \), and \( \mathbf{S}^k \), we only plot partial entries, that is, \( u_{i,i}, v_{i,i} \) and \( s_{i,i} \). As the rank is 10, there are ten curves for \( \mathbf{U}^k \) and \( \mathbf{V}^k \). Besides, the number of curves for \( \mathbf{S}^k \) is much less than 400 because of its sparsity. It is observed that the sequence \( \{\mathbf{U}^k, \mathbf{V}^k, \mathbf{S}^k\} \) is able to converge within 10 iterations.

Moreover, we investigate the impact of initialization, namely, \( \mathbf{V} \), in 50\% randomly missing data and 3dB GMM noise. Fig. (S.4) plots 100 convergence curves for each algorithm where \( \mathbf{V} \) are randomly initialized. Specifically, the average steady-state MSEs of the \( \ell_0 \)-BCD-F and \( \ell_0 \)-BCD are 5.4582\times10^{-2} and 5.4592\times10^{-2}, respectively. Hence, their performance seems insensitive to the parameter initialization.

2) Performance Comparison: We compare the \( \ell_0 \)-BCD-F and \( \ell_0 \)-BCD with popular methods, including \( \ell_p \)-reg [25], \( \ell_p \)-ADMM [25], M-estimation [27], VBMFL1 [31], and ORMC [22]. Fig. 1 depicts the MSE convergence performance of different methods under 50\% randomly missing data and additive GMM noise of SNR = 3dB. It is observed that the \( \ell_0 \)-BCD-F and \( \ell_0 \)-BCD have a similar steady-state MSE which is lower than that of the competing algorithms. Hence, the proposed methods have superior recovery performance over the existing approaches. As the ORMC is designed for the situation that the observed matrix has a few Gaussian noise-contaminated columns, it cannot achieve satisfactory performance in impulsive noise.
The runtimes are tabulated in Table II where the stopping condition is MSE < 0.1. Since the ORMC cannot attain this criterion, its result is not presented. We see that the elapsed time of our algorithms is much less than that of the competitors. In addition, the $\ell_0$-BCD-F is faster than $\ell_0$-BCD.

The impact of the percentage of missing data with 3dB GMM noise is plotted in Fig. 2. We see that the MSEs of $\ell_0$-BCD-F and $\ell_0$-BCD are the smallest among the seven algorithms for all percentages. Thus, our methods achieve superior recovery performance over the $\ell_p$-reg, $\ell_p$-ADMM, M-estimation, VBMFL1, and ORMC. It is worth noting that the $\ell_0$-BCD-F has comparable performance to $\ell_0$-BCD, indicating that the scheme of discarding the outlier-contaminated entries is feasible.
Fig. 3: MSE versus SNR by different algorithms with 50% randomly missing data.

The performance under different SNRs is investigated in Fig. 3. As the MSEs of the ORMC are too large such that it is difficult to differentiate the remaining algorithms, its results are not included. We clarify that, under 9dB GMM noise, the MSEs of the $\ell_0$-BCD-F, $\ell_0$-BCD, $\ell_p$-reg, $\ell_p$-ADMM, M-estimation and VBMFL1 are 0.01427, 0.01434, 0.01996, 0.02074, 0.01791, and 0.01737, respectively. It is seen that our developed methods outperform the competing algorithms at different levels of the impulsive noise.

B. Image Inpainting

A popular application of MC is gray-scale image inpainting [26]. Images, in practice, may not be fully captured due to damage to the photosensitive device or the shadow from other objects. In addition, the image data may be mixed with impulsive noise during wireless transmission or bit errors in the signal acquisition stage. Although the impulse amplitude may be very large, they are set to the largest or smallest admissible values after quantization, giving the image a “salt and pepper” like appearance. For 8-bit images, the maximum and minimum values are 0 (black) and 255 (white), respectively. The salt-and-pepper noise has a noise density coefficient, denoted as $\tau$. Note that the relationship between $\tau$ and SNR is $\tau = 1/\text{SNR}$ [25]. For a given value of $\tau$, approximately $0.5\tau$ of the pixels become 255 or 0. Fig. 4 shows the noiseless and noisy pictures at $\tau = 0.2$.

It is worth mentioning that the PDF of the salt-and-pepper noise does not comply with GMM and hence the proposed algorithms cannot be directly adopted to resist the salt-and-pepper noise. Since the pixels which are corrupted by salt-and-pepper noise are either 255 or 0, it is easy to detect the location of outliers. In general, dispersed black and white pixels are not the integers of 0 and 255, respectively, but have values close to 0 and 255. If there exists an area of white or black, it is not difficult to differentiate it and the salt-and-pepper noise. This is because that the noise is discrete, while the area is continuous. Therefore, we directly utilize 255 and 0 to identify the salt and pepper pixels, which is also adopted by [53]. Based on
Fig. 4: Illustration of original image and noisy image corrupted by salt-and-pepper noise with SNR = 5dB.

Fig. 5: Performance of different approaches in two types of masks with 5dB salt-and-pepper noise. The left column shows observed pictures with different masks, while the recovered images are shown from the second column to the end.

the above strategy, (13a)–(13c) are simplified as

\[
U^{k+1} = \arg\min_u \|X_\Omega - (UU^k)\Omega - S^k_\Omega\|_F^2, \tag{43a}
\]

\[
V^{k+1} = \arg\min_v \|X_\Omega - (UU^{k+1})\Omega - S^k_\Omega\|_F^2, \tag{43b}
\]

\[
S^{k+1} = X_\Omega - (UU^{k+1})\Omega, \tag{43c}
\]

where $\Omega^o \in \mathbb{R}^{m \times n}$ is the subset of $\Omega$, and contains the indices of outliers. Similarly, (26a)–(26c) can be re-expressed as

\[
U^{k+1} = \arg\min_u \|(UU^k)\Omega - X_\Omega\|_F^2, \tag{44a}
\]

\[
V^{k+1} = \arg\min_v \|(UU^{k+1})\Omega - X_\Omega\|_F^2. \tag{44b}
\]

It is seen that RMC is converted into a tractable problem with the salt-and-pepper noise.

One image, called windows, is first used to compare the proposed algorithms with existing approaches, including $\ell_p$-reg, $\ell_p$-ADMM, M-estimation, VBMFL1 and ORMC. All algorithms use the same rank of 10. Fig. 4 shows the original image and the noisy image with salt-and-pepper noise. The recovery performance is measured by two metrics, namely, peak SNR (PSNR) and structural similarity (SSIM). They can be computed by the built-in MATLAB commands, i.e., `psnr(recovered, original)` and `ssim(recovered, original)`. Larger values of PSNR and SSIM mean that the recovery performance is better.

</table>

namely, random and fixed masks are investigated. The random mask implies that the image has 50% randomly distributed missing entries, while the fixed mask contains the distorted text of “matrix completion”. It is observed that the PSNRs and SSIMs of \(\ell_0\)-BCD and \(\ell_0\)-BCD-F are larger than those of the competing algorithms. Hence, the devised methods outperform the existing approaches in these two missing pattern.
Moreover, the impact of the percentage of randomly missing data on recovery performance is tabulated in Table III under 5dB salt-and-pepper noise. We see that the PSNRs and SSIMs of the proposed methods are higher than those of \(\ell_p\)-reg, \(\ell_p\)-ADMM, M-estimation, VBMFL1 and ORMC in different ratios.

Furthermore, eight well-known images, depicted in Fig. 6, are selected to evaluate the inpainting performance. Each picture is evaluated with the random and fixed masks under the previous settings. The comparison results are tabulated in Table IV. It is seen that, in most cases, the \(\ell_0\)-BCD and \(\ell_0\)-BCD-F show remarkable superiority over their competitors. In a few cases, the metric values of the suggested algorithms are slightly smaller than those of the existing methods, such as the PSNR of the \(\ell_0\)-BCD-F in Image-3, as well as SSIM of \(\ell_0\)-BCD in Image-7 and Image-8 in the text mask scenarios.

C. Nonnegative Synthetic data

In this subsection, \(\ell_0\)-BCD-MM and \(\ell_0\)-BCD-MM-F are examined using synthetic data. A noise-free matrix \(X \in \mathbb{R}^{400 \times 500}\) of \(r = 10\) is generated by the product of \(|X_1| \in \mathbb{R}^{400 \times 10}\) and \(|X_2| \in \mathbb{R}^{10 \times 500}\) where entries of \(X_1\) and \(X_2\) satisfy the standard Gaussian distribution. We randomly select 50% entries of \(X\) as the incomplete observations and then add GMM noise of SNR = 6dB. Two methods, namely, MF-ADMM [38] and LRA-ADMM [39], are compared with our approaches.

![Fig. 7: MSE versus iteration number with 50% missing data and 6dB GMM noise.](image)

Fig. 7 illustrates the MSE convergence performance. It is observed that the recovery errors of the two proposed methods are lower than those of the competing algorithms. This is because the MF-ADMM and LRA-ADMM do not take impulsive noise into account in their formulation.

D. Hyperspectral Imaging

There are two approaches to solve hyperspectral imaging, namely, matrix-based and tensor-based methods. Comparison of these two strategies is studied in [54]. The results show that matrix-based methods outperform tensor-based approaches when the spectral bands are sufficient. This is because restoring unobserved entries
Fig. 8: Original images of Salinas and Indian pines scenes, and corresponding incomplete images with 30% randomly missing data and 6dB GMM noise.

Fig. 9: Recovered images by $\ell_0$-BCD-MM-F, $\ell_0$-BCD-MM, LRA-ADMM and MF-ADMM using Salinas dataset.

are difficult at a certain frequency based on the same location in other frequencies when spectral bands are limited.

In this subsection, we apply the proposed matrix-based algorithms to restore hyperspectral data. Two open-source datasets are utilized, i.e., Indian pines and Salinas scene\(^1\) whose dimensions are $145 \times 145 \times 200$ and $200 \times 200 \times 200$, respectively. The dimensions of $145 \times 145 \times 200$ imply that the hyperspectral dataset has 200 spectral bands or slices, and each slice has the dimensions of $145 \times 145$. Prior to handling hyperspectral image inpainting, it requires reshaping each slice into a vector and then combining all vectors into a matrix. Furthermore, the incomplete matrix and observed matrix with GMM noise can be generated.

Two slices of each dataset are selected to evaluate the recovery performance, including the 90th and 175th slices. Fig. 8 shows the original images of Salinas and Indian pines scenes as well as the corresponding observed images with 30% randomly missing data and 6dB GMM noise. The visual presentation of Salinas is shown in Fig. 9. Moreover, the results of the Indian pines are depicted in Fig. 10. It is seen that the

\(^1\)URL: http://www.ehu.eus/ccwintco/index.php/Hyperspectral_Remote_Sensing_Scenes
PSNRs and SSIMs of the proposed methods are much higher than those of MF-ADMM and LRF-ADMM. Therefore, our algorithms attain better recovery performance than the existing approaches.

VI. Conclusion

In this paper, we exploit the entry-wise $\ell_0$-norm and matrix factorization for RMC. The principle is that outliers are separated from the observed matrix by a $\ell_0$-norm regularization term. Besides, the penalty parameter of the $\ell_0$-norm is automatically updated during the iterative procedure. The resultant multivariable optimization problem is solved by BCD, yielding two algorithms, namely, $\ell_0$-BCD and $\ell_0$-BCD-F. In the $\ell_0$-BCD, anomalies are discerned and separated from the observed matrix, while the $\ell_0$-BCD-F treats the outlier-contaminated data as unobserved entries. Our RMC approach is extended to solve RNMC where the nonnegativity constraint is handled by MM. Then, $\ell_0$-BCD-MM and $\ell_0$-BCD-MM-F are proposed for RNMC. Simulation results on synthetic and real-world data demonstrate the superiority of our algorithms over the state-of-the-art methods in terms of recovery accuracy and computational efficiency. Although the convergence of the objective value $\{\mathcal{L}(U^k, V^k, S^k)\}$ has been proved, we will establish sequence convergence of BCD for the nonconvex and noncontinuous objective function in the future work.

Appendix A

Convergence Analysis of Algorithm 1

Before the analysis of the objective value convergence of Algorithm 1, we define a loss function $\mathcal{L}_{\mu^k}(U^k, V^k, S^k) = \|X - (U^k V^k)\Omega - S^k\|_F^2 + \mu^k\|S^k\|_0$. It is clear that $\mathcal{L}_{\mu^k}(U^k, V^k, S^k)$ is lower bounded by zero. To prove the objective value convergence, we need to show that the update of each variable by Algorithm 1 keeps
its value nonincreasing.

\[ L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^{k+1}) - L_{\mu}^k(U^k, V^k, S^k) \]
\[ = L_{\mu}^k(U^{k+1}, V^k, S^k) - L_{\mu}^k(U^k, V^k, S^k) \]
\[ + L_{\mu}^k(U^{k+1}, V^{k+1}, S^k) - L_{\mu}^k(U^{k+1}, V^k, S^k) \]
\[ + L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^{k+1}) - L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^k). \]  \hspace{1cm} (45)

Since \( U^{k+1} \) is determined by (15), it minimizes \( L_{\mu}^k(U, V^k, S^k) \), resulting in
\[ L_{\mu}^k(U^{k+1}, V^k, S^k) - L_{\mu}^k(U^k, V^k, S^k) \leq 0. \] In addition, \( V^{k+1} \) and \( S^{k+1} \) are the optimal solutions to \( \min V L_{\mu}^k(U^{k+1}, V^k, S^k) \) and \( \min S L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^k) \), respectively. Therefore, \( L_{\mu}^k(U^{k+1}, V^{k+1}, S^k) - L_{\mu}^k(U^{k+1}, V^k, S^k) \leq 0 \) and \( L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^{k+1}) - L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^k) \leq 0 \) hold. For update of \( \mu^k \), it is nonincreasing as described in Algorithm 1 and hence it makes
\[ L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^k) - L_{\mu}^k(U^{k+1}, V^{k+1}, S^k) \leq 0 \] Thereby, \( L_{\mu+1}^k(U^{k+1}, V^{k+1}, S^{k+1}) - L_{\mu}^k(U^k, V^k, S^k) \leq 0 \) holds, implying that \( \{ L_{\mu}^k(U^k, V^k, S^k) \} \) is nonincreasing. Furthermore, the objective function is upper bounded by \( L_{\mu,0}^k(U^0, V^0, S^0) \), and lower bounded by 0. As a result, \( \{ L_{\mu}^k(U^k, V^k, S^k) \} \) generated by \( \ell_0 \)-BCD is convergent.

Appendix B

Proof of Closed-Form Solution to Problem (36)

Since (36) is a quadratic programming problem with convex constraint, the KKT conditions are sufficient and necessary for its optimal solution. Thereby, we derive the solution using the KKT conditions. For the sake of presentation simplicity, we omit the superscripts of \( u \) and \( q \). Then, the Lagrangian of (36) is
\[ \gamma(u, v) = u^T u + q^T u - v^T u, \] \hspace{1cm} (46)
where \( v \) contains the Lagrange multipliers. The derivative of \( \gamma(u, v) \) w.r.t. \( u \) is \( 2u + q - v \). Thus, the solution is
\[ u_i = \frac{1}{2}(\nu_i - q_i). \] \hspace{1cm} (47)

Based on the KKT conditions, we discuss three cases:

(i) \( q_i > 0 \): It must hold that \( \nu_i \geq q_i > 0 \) due to the primal feasibility: \( u_i \geq 0 \). Hence, \( \nu_i > 0 \) and then necessarily \( u_i = 0 \) according to the complementary slackness condition.

(ii) \( q_i < 0 \): From the dual feasibility condition, we get \( \nu_i \geq 0 \), which results in \( u_i > 0 \). Moreover, the complementary slackness condition requires \( u_i\nu_i = 0 \). Thus, we have \( \nu_i = 0 \) and thereby \( u_i = -q_i/2 \).

(iii) \( q_i = 0 \): According to the complementary slackness condition, we conclude \( u_i = \nu_i = 0 \).

The compact expression of the solution is thus:
\[ u_i = \begin{cases} -\frac{q_i}{2}, & \text{if } q_i < 0 \\ 0, & \text{otherwise}. \end{cases} \] \hspace{1cm} (48)
