We propose an unified $\lambda$-subdivision scheme with a continuous family of tuned subdivisions for quadrilateral meshes. Main subdivision stencil parameters of the unified scheme are represented as spline functions of the subdominant eigenvalue $\lambda$ of respective subdivision matrices and the $\lambda$ value can be selected within a wide range to produce desired properties of refined meshes and limit surfaces with optimal curvature performance in extraordinary regions. Spline representations of stencil parameters are constructed based on discrete optimized stencil coefficients obtained by a general tuning framework that optimizes eigenvectors of subdivision matrices towards curvature continuity conditions. To further improve the quality of limit surfaces, a weighting function is devised to penalize sign changes of Gauss curvatures on respective second order characteristic maps. By selecting an appropriate $\lambda$, the resulting unified subdivision scheme produces anticipated properties towards different target applications, including nice properties of several other existing tuned subdivision schemes. Comparison results also validate the advantage of the proposed scheme with higher quality surfaces at lower $\lambda$ values, a challenging task for other related tuned subdivision schemes.

1 INTRODUCTION

Subdivision schemes provide an elegant solution for the representation of models with arbitrary topology. With a given set of subdivision rules, an input mesh is subdivided to generate a series of refined meshes that converge to a smooth limit surface. Subdivision schemes relax the rigid grid structure of B-spline control meshes and allow the use of extraordinary vertices (EVs) on a quadrilateral control mesh with the number of incident edges meeting at an internal extraordinary vertex (EV) being three or more than four. The number of edges connected to a vertex is usually called its valence. A popular subdivision scheme for quadrilateral meshes is the Catmull-Clark subdivision [Catmull and Clark 1978] which has been integrated in various modeling software, such as Rhino, Blender and Maya, for model definition using unstructured meshes with arbitrary topology.
The properties of Catmull-Clark subdivision at extraordinary vertex positions, however, can be further improved for some practical applications. First, Catmull-Clark subdivision cannot produce bounded curvature near extraordinary points [Sabin et al. 2003], which is a necessary condition for producing high quality limit surfaces with $C^2/G^2$ continuity conditions. Second, Catmull-Clark surfaces might exhibit kinked highlight lines indicating less competitive surface qualities. Third, Catmull-Clark subdivision cannot reproduce convex shapes [Karciauskas et al. 2004] for generic data when the valence is $N \geq 5$. To remedy these problems, a simple idea is to directly modify subdivision rules so that the resulting subdivision scheme preserves desired properties. Such a method is usually referred to as subdivision tuning. Subdivision rules as linear operations of vertices can be written in a matrix form, and the operation of local mesh subdivision can be performed through a matrix multiplication operation between the subdivision matrix and the array of local control vertices. As subdivision surfaces can be considered as infinitely refined control meshes, surface properties can thus be determined by the eigenstructure of respective subdivision matrices. Tuning of subdivision schemes is thus to modify subdivision rules so that the eigenstructure of the subdivision matrix follows specific patterns that lead to desired properties of limit surfaces.

A key parameter in the eigenstructure analysis of subdivision matrices is the subdominant eigenvalue $\lambda$, i.e., the twofold second largest eigenvalue that has paramount importance in subdivision tuning. Tuned subdivision schemes usually produce different $\lambda$ values suitable for different target applications. Intuitively, $\lambda$ quantifies the speed of contraction for 1-ring vertices in the process of subdivision. As illustrated in Fig. 1, a lower $\lambda$ value leads to faster contraction of 1-ring vertices. Existing tuned subdivision schemes with high surface qualities, e.g., [Augsdörfer et al. 2006] and [Ma and Ma 2018], usually result in polar artifacts in the mesh structure which might cause inconveniences for rendering [Augsdörfer et al. 2009] due to slightly higher $\lambda$ values. At $\lambda = 0.5$, polar artifacts could be eliminated with uniform refined meshes [Ma and Ma 2019b], see Fig. 1, at the expense of slightly reduced limit surface qualities. So in practice, subdivision schemes with intermediate $\lambda$ values might be necessary for different modeling and graphics applications to balance between different desired priorities. In recent years, subdivision schemes have also been widely applied in engineering analysis. The use of subdivision schemes with a lower $\lambda$ value usually produces analysis results with faster convergence of solution errors [Ma and Ma 2019a; Wei et al. 2021], and the use of subdivision schemes at different $\lambda$ values would also be preferred for producing different target analysis solutions.

These observations motivate us to develop a continuous family of $\lambda$-subdivision schemes that cover a wide range of $\lambda$ values to accommodate different applications. Inspired by the clear geometric meaning of the subdominant eigenvalue $\lambda$, we use $\lambda$ as an intuitive indexing parameter to extract respective subdivision schemes with specific subdominant eigenvalue $\lambda$. For ease of implementation, main subdivision coefficients are written as spline functions of $\lambda$. By selecting an appropriate $\lambda$ value, the respective tuned subdivision scheme can be extracted by simple spline evaluation and follow-up arithmetic calculations. As to the selection of appropriate $\lambda$ values for different target applications, results of several featured $\lambda$-subdivisions are provided as illustrations for guiding the selection. Main features and contributions of this work are as follows.

- This paper presents a novel unified $\lambda$-subdivision scheme with a continuous family of tuned subdivision schemes unified under a single parameter $\lambda$ that has explicit and intuitive meanings for various practical applications.
- Main subdivision coefficients of the unified $\lambda$-subdivision scheme are represented as spline functions in $\lambda$. For a given $\lambda$ value, the full set of respective subdivision parameters can be easily extracted through spline evaluations and further simple arithmetic calculations.
- The proposed unified $\lambda$-subdivision scheme includes tuned subdivisions with better or similar properties to that in [Ma and Ma 2018], [Ma and Ma 2019b] and [Ma and Ma 2019a]. In addition, one can extract tuned subdivision schemes in a continuous wide range of $\lambda$ for various practical applications in modeling, computer graphics and engineering analysis.
- The proposed unified subdivision scheme generates tangent plane continuous limit surfaces at extraordinary points with optimal or near optimal curvature performances for any feasible $\lambda$ by optimization towards curvature continuity conditions. To accommodate wider applications, the feasible domain of $\lambda$ is expanded to lower $\lambda$ region by proper relaxation of bounded curvature constraints.
- We also construct a weighted objective function to further improve surface qualities at lower $\lambda$ values, e.g., [Ma and Ma 2019a]. The new objective function includes weighting functions that penalize undesired sign changes of Gauss curvatures of second order maps for better surface performances.

The rest of the paper is organized as follows. Some further preliminaries on subdivision-based modeling and other related works can be found in Section 2. To construct a continuous family of the proposed subdivision schemes, we first perform subdivision tuning at a set of discrete $\lambda$ values in Section 3. Spline representations of main subdivision coefficients in $\lambda$, the so-called subdivision stencils, are further constructed from the resulting discrete tuned subdivision schemes in Section 4. Subdivisions at some featured $\lambda$ values with method for the evaluation of the full set of stencil parameters at an arbitrary $\lambda$ value are also highlighted in Section 4. Examples and some further discussions with comparisons can be found in Section 5. Conclusions and future works are discussed in Section 6.

2 RELATED WORK

2.1 Subdivision prerequisites

Subdivision schemes work by recursive refinement of input meshes producing a sequence of refined meshes converging to smooth limit surfaces. Each of refined vertices is computed as linear combinations of vertices in the old mesh, and coefficients that describe the influence from old vertices to a new vertex is referred to as a subdivision stencil [Sabin et al. 2007], as illustrated in Fig. 2. Subdivision of a given mesh can be performed by matrix multiplication, and the limit properties of subdivision surfaces can be analyzed through the spectrum of subdivision matrices. With proper organization of local control vertices, the respective subdivision matrix $S$ is usually block-circulant that can be transformed to a block-diagonal form $S$.
through the help of Discrete Fourier transform [Ball and Storry 1988].

Eigenvalues of subdivision matrix $S$ can thus be computed by solving eigenvalues of the diagonal submatrices in $S$ which is much easier, and if the eigenvalue $\lambda_1$ is an eigenvalue of the $k$-th diagonal block in $S$, then $\lambda_1$ has a Fourier index of $k$, denoted by $F(\lambda_1) = \{k\}$ [Peters and Reif 2008]. For a general subdivision scheme with smooth limit surfaces, the first three eigenvalues in descending order should be $1, \lambda, \lambda$, and $\lambda < 1$ is called the subdominant eigenvalue. Similarly, the one after $\lambda$ is called the subsubdominant eigenvalue. There are two right eigenvectors $v_1$ and $v_2$ for the subdominant eigenvalue $\lambda$, which can be considered as lists of two coordinates of vertices in $\mathbb{R}^2$.

The set of vertices form the natural configuration of the subdivision scheme, see Fig. 1, and the spline rings defined by the natural configuration is referred to as the characteristic map [Reif 1995]. Similarly, higher order maps can be defined if we consider the eigenvector for the subdominant eigenvalue as the third coordinate, see Fig. 4(b). Limit properties, e.g., $C^1$ continuity, can be analyzed through analysis of characteristic maps, while higher order properties are related to higher order maps. For a comprehensive tutorial on subdivision surfaces, please refer to [Zorin 2000] [Peters and Reif 2008].

2.2 Unified subdivision schemes

With the introduction of Catmull-Clark subdivision [Catmull and Clark 1978] and Doo-Sabin subdivision [Doo and Sabin 1978], a wide range of subdivision schemes have been further proposed, including Loop subdivision [Loop 1987], $\sqrt{2}$-subdivision [Li et al. 2004], $\sqrt{3}$-subdivision [Kobbelt 2000], Butterfly subdivision [Dyn et al. 1990], Kobbelt subdivision [Kobbelt 1996], and so on. For further introduction on subdivision schemes, please refer to [DeRose et al. 1998; Reif and Sabin 1991; Sabin 2005] and references therein for information. These subdivision schemes are mostly further generalization of certain class of splines or other basis functions. In the literature, there are also families of unified subdivision schemes that are proposed to unify and further generalize various individual classes of subdivision schemes, aiming at (1) subdivision with arbitrary continuity in regular regions [Stam 2001] [Zorin and Schröder 2001] [Deng and Ma 2013]; (2) generalizations of interpolatory and approximating subdivisions [Maillot and Stam 2001] [Shi et al. 2008] [Zhang et al. 2019] [Novara and Romani 2016]; (3) subdivision for mixed triangle/quad meshes [Stam and Loop 2003] [Lin et al. 2013] [Peters and Shiue 2004]; and (4) unifications for existing non-stationary schemes [Zheng and Zhang 2017]. In this work, we present a unified $\lambda$-subdivision scheme that can be considered as a generalized unification of several existing tuned subdivision schemes, such as [Ma and Ma 2018], [Ma and Ma 2019b], and [Ma and Ma 2019a] for different target applications.

2.3 Limit surface properties of subdivision schemes

Properties of subdivision surfaces can be analyzed from the eigen-structures of the respective subdivision matrices [Doo and Sabin 1978]. A sufficient condition for $C^4$ continuity at extraordinary positions is given in [Reif 1995] that requires two identical subdominant eigenvalues, denoted by $\lambda$, and regular and injective characteristic maps. It has been verified that Catmull-Clark, Doo-Sabin, and Loop schemes, satisfy the $C^4$ condition and thus are $C^1$ continuous at extraordinary positions [Peters and Reif 1998] [Umlauf 2000].

For surfaces to be $C^k$ continuous at extraordinary positions, a lower bound for the degree of respective polynomial patches is given in [Prautzsch and Reif 1999], and a stationary subdivision scheme requires a minimum degree of 6 to be curvature continuous at extraordinary positions. The Catmull-Clark scheme is thus only $C^1$ continuous at extraordinary positions, and the curvatures are unbounded [Karčiauskas et al. 2004]. Criteria for bounded curvature are presented in [Doo and Sabin 1978] and subdivision rules can be tuned to satisfy such properties. Although curvatures may not be bounded for Catmull-Clark subdivision near extraordinary positions, the principle curvatures are square-integrable [Reif and Schröder 2001], indicating that the scheme can be used for engineering analysis. There are also other constructions for $C^2$ continuity at extraordinary positions, e.g., guided subdivision [Karčiauskas and Peters 2007] [Karčiauskas and Peters 2018] and patchwork methods [Loop and Schaefer 2008] [Ma and Ma 2020] [Yang et al. 2023]. These schemes may produce higher-quality limit surfaces at the cost of higher complexity for implementation. Patchwork methods may not always produce nested limit surfaces.

2.4 Tuning of subdivision schemes

Subdivision coefficients can be tuned to have desired properties. The Catmull-Clark scheme and the Loop scheme are tuned for bounded curvature in [Sabin 1991] and [Loop 2002], respectively, and bounded curvature is also achieved for non-uniform subdivisions [Cashman et al. 2009b]. To incorporate a wider range of possible desired properties, a general tuning framework through optimization of eigenvectors is proposed in [Bartel and Kobbelt 2004] that produces surfaces with bounded curvature and alleviated polar artifact. Performances of limit surfaces at extraordinary positions can be further improved by optimizing respective eigenvectors towards curvature continuity conditions while maintaining minimum curvature variations [Ma and Ma 2018] and least polar artifact [Ma and Ma 2019b]. In [Augsdörfer et al. 2006], the Gauss curvature near extraordinary positions is minimized through optimization of Gauss curvatures on a set of representative central surfaces.

2.5 Tuning for applications in Isogeometric Analysis (IGA)

With the popularity of subdivision in engineering analysis, tuning of subdivision schemes for analysis purposes have attracted much attention. In [Zhang et al. 2018], the Catmull-Clark scheme is tuned through optimization of second order characteristic maps using a thin-plate energy, and the tuned scheme yields a significant reduction of solution errors in $L^2$-norms. For higher convergence rates in isogeometric analysis (IGA), a lower subdominant eigenvalue of $\lambda = 0.39$ is used in [Ma and Ma 2019a] to increase local mesh densities near extraordinary vertices, and optimal convergence rates are observed for $L^2$-approximation problems. Similar ideas are also used for tuning of non-uniform subdivisions in [Li et al. 2019] [Wei et al. 2021] and Loop subdivision in [Kang et al. 2022]. In general, these schemes require $\lambda$ values lower than 0.5 which might be undesirable for high quality limit surfaces. Further discussions on subdivision for IGA applications can also be found in [Dietz et al. 2023].
2.6 Other tuning and construction schemes

To balance between surface qualities and engineering analysis, a tuned scheme [Wang and Ma 2023] further relaxes Catmull-Clark rules for 2-ring refined vertices so that additional degrees of freedom are introduced in optimization for improved surface qualities at the cost of increased complexity in implementation for both tuning and later applications. In the literature, one can also find special rules for 2-ring refined vertices in [Karčiauskas and Peters 2023a][Karčiauskas and Peters 2023b][Karčiauskas and Peters 2022] that are constructed based on the idea of guided subdivision [Karčiauskas and Peters 2007] with refined vertices that are dependent on all 3-ring vertices, leading to much more degrees of freedom for improving desired limit surface properties and with well behaved limit surface quality benefiting both modeling and relevant applications.

3 CONSTRUCTION OF SUBDIVISION STENCILS AT SPECIFIED $\lambda$ VALUES

In this section, we present a general tuning framework to compute stencil coefficients through optimization towards curvature continuity conditions at extraordinary positions. The tuning framework is similar to that in [Ma and Ma 2018], but a different weighted objective function with integrated penalty for reducing sign changes in Gauss curvature of the second order characteristic maps is used for stencil optimization in this work, which leads to improved properties of limit surfaces, especially for subdivision at lower $\lambda$ values.

3.1 Subdivision stencils and subdivision matrices

The proposed family of subdivision schemes generalizes Catmull-Clark subdivision [Catmull and Clark 1978] by modifying subdivision rules for 1-ring refined vertices. The respective stencil coefficients are written as functions of $\lambda$, the subdominant eigenvalue of respective subdivision matrices. The symbolized subdivision stencils are illustrated in Fig. 2. For simplicity, we omit the variable $\lambda$ of subdivision coefficients sometimes, and use $f_1$, $f_2$, etc., instead.

The subdivision stencils in Fig. 2 are for quadrilateral meshes of arbitrary topology with separated extraordinary vertices. In cases of input meshes with general topological structure or quadrilateral meshes with connected extraordinary vertices, we can subdivide the mesh once using Catmull-Clark rules [Catmull and Clark 1978] to separate extraordinary vertices, and the proposed unified subdivision scheme can thus be applied.

Based on the irregular rules in Fig. 2 and regular rules for Catmull-Clark subdivision, local subdivision matrices, denoted by $S$, can be constructed to perform local mesh subdivision, written as

$$\bar{P}_m = S \bar{P}_{m-1},$$

where $\bar{P}_m$ is the vector of control vertices at level $m = 0, 1, 2, \ldots$.

The respective eigenvalues and eigenvectors of the subdivision matrix $S$ can be explicitly written as functions of subdivision stencils in Fig. 2, which will be further used for subsequent tuning of desired subdivision stencils. A detailed formulation of subdivision matrices with eigenstructure analysis can be found in the attached supplementary materials (Section A).

Fig. 2. Symbolized subdivision stencils near an extraordinary vertex: (a)-(c) stencil coefficients for refined face, edge, and vertex vertices, respectively. Hollow circles are regular vertices from the original mesh and red pentagram represents the extraordinary vertex in the original mesh. Red, blue and green solid circles are the refined face, edge, and vertex vertices, respectively. Note that all subdivision coefficients can be written as functions of subdominant eigenvalues $\lambda$, respectively, and details will be given in Section 4.

3.2 Expected properties for subdivision schemes

For a given subdivision scheme, properties of limit surfaces are closely related to eigenstructures of the respective subdivision matrices. In the following, we highlight relevant conditions and requirements of respective eigenstructures for meeting expected properties of desired subdivision schemes, which will be used for later stencil tuning and optimization. For clarity, eigenvalues of the local subdivision matrix $S$ are arranged with descending absolute values as $|\lambda_0| \geq |\lambda_1| \geq |\lambda_2| \geq \cdots$.

3.2.1 Convergence. The subdivision scheme converges and is affine invariant [Doos and Sabin 1978] if and only if

$$1 = \lambda_0 > |\lambda_1|, \quad \mathcal{F}(1) = \{0\}. \quad (2)$$

3.2.2 $C^1$ continuity. The subdominant eigenvalue $\lambda$ is positive and has algebraic and geometric multiplicity two, with Fourier indices $1, N-1$,

$$1 > \lambda := \lambda_1 = \lambda_2 > |\lambda_3|, \quad \mathcal{F}(\lambda) = \{1, N-1\}, \quad (3)$$

and the characteristic map defined by the corresponding eigenvectors is regular and injective [Peters and Reif 1998].

3.2.3 Convex hull property. All subdivision stencils in Fig. 2 should be nonnegative, i.e.,

$$f_1, f_2, f_5, d_1, d_2, e_1, e_2, 1 - \alpha - \beta, \alpha, \beta \geq 0. \quad (4)$$

Note that the variable $\lambda$ in these stencils is omitted for brevity.
3.2.4 Bounded curvature. The subdominant eigenvalue \( \mu \) is positive and has algebraic and geometric multiplicity three with Fourier indices 0, 2, \( N-2 \),

\[
1 > \lambda := \lambda_1 = \lambda_2 > \mu = \lambda_3 = \lambda_4 > |\lambda_5|, \quad \mathcal{F}(\mu) = \{0, 2, N-2\},
\]

and satisfies \( \mu = \lambda^2 \) [Doo and Sabin 1978][Reif 2007].

3.2.5 \( C^2 \) continuity. The necessary and sufficient conditions [Reif 2007][Peters and Reif 2008] for a subdivision surface to be \( C^2 \) at an extraordinary position for all generic initial data is given as

1. \( \mu < \lambda^2 \),
2. \( \mu = \lambda^2 \) and \( \psi_i \in \text{span}(\psi_1^2, \psi_1 \psi_2, \psi_2^2) \) for all \( i = 3, \ldots, q \).

The second condition can be written as

\[
\psi_i = a_1 \psi_1^2 + b_1 \psi_1 \psi_2 + c_1 \psi_2^2, \quad i = 3, \ldots, q.
\]  

where \( \psi_i \) is the eigenfunctions corresponding to \( \lambda_i \), and \( q \leq 5 \) due to the linear independence. At least triple subdominant eigenvalues with Fourier indices \( \{0, 2, N-2\} \) are required to produce all possible basic shapes, which are always satisfied by our scheme.

3.3 Stencil optimization with desired properties

The subdivision tuning can be performed through an optimization framework with objective functions being the main expected properties subjecting to a group of necessary constraints for stencil coefficients to meet other desired properties of subdivision schemes.

3.3.1 Selection of free variables for optimization. Some of the aforementioned properties can be strictly satisfied, such as convergence of refined meshes, \( C^1 \) continuity, the convex hull property, and bounded curvature. These properties usually lead to hard constraints in the optimization of stencil coefficients.

As illustrated in Fig. 2, there are nine subdivision coefficients, i.e., \( f_1, f_2, f_3, d_1, d_2, e_1, e_2, \alpha, \beta \). If all the hard constraints are satisfied, seven degrees of freedom will be eliminated, leaving only two independent parameters for optimization. In this work, we choose \( f_1 \) and \( f_3 \) to be the stencil coefficients for face vertices, as independent variables, and other coefficients for prescribed \( N \) and \( \lambda \) can be written as functions of \( f_2 \) and \( f_5 \) in terms of

\[
(f_1, d_1, d_2, e_1, e_2, \alpha, \beta) = \mathbf{L}(N, \lambda, f_2, f_5).
\]

Detailed expression for Eq. (7) can be found in Eqs. (25)-(28) and in Section 4.5, and hard constraints can be transformed into parameter bounds of the following form

\[
\mathbf{G}(N, \lambda, f_2, f_5) \leq 0,
\]

where details are given in supplementary materials (Section B).

3.3.2 Constraint relaxation for bounded curvature at lower \( \lambda \) values.

The lower bounds \( \lambda_1 \) for \( \lambda \) of valences \( N = 3, \ldots, 20 \) to produce schemes with bounded curvature are illustrated in Fig. 3. If bounded curvature is strictly required, one can only select \( \lambda \) in a narrow range, especially for higher valences. To further extend feasible domains for \( \lambda \), the bounded curvature constraint is relaxed as

\[
\mu = \alpha \lambda^2,
\]

where \( s \geq 1 \) is a relaxation coefficient for the bounded curvature criterion of \( \mu = \lambda^2 \). In this work, the value of \( s \) is computed as

\[
s = s_f + \Delta s,
\]

where \( s_f \) is the lower bound for \( s \) to satisfy other desired properties and \( \Delta s \) is a small tolerance necessary in eigenstructure analysis. The lower bounds \( s_f \) for all valences have consistent forms with explicit formula in Eq. (47) given in the supplementary materials (Section B). A typical \( s = \lambda \) curve is illustrated in Fig. 6(e) for valence \( N = 6 \). We empirically select \( \Delta s = \Delta \lambda_0 = 10^{-3} \) at \( \lambda \leq \lambda_1 \) and \( \Delta s = 0 \) at \( \lambda \geq \lambda_1 + \Delta \lambda_0 \) in this work, where \( \Delta \lambda_0 = 10^{-2} \). Further investigations regarding the selection of \( s \) for producing well behaved subdivisions will be conducted in our future work.

3.3.3 The objective function for optimization. The requirements for \( C^2 \) continuity are adapted to construct the objective function for stencil optimization. The \( C^2 \) continuity condition in Eq. (6) requires computations of eigenfunctions \( \psi_i \) for eigenvalues \( \lambda \) and \( \mu \). The eigenfunction \( \psi_i \) has intuitive geometric meanings. If we consider eigenvectors of \( \lambda \) as arrays of coordinates for control vertices, the resulting subdivision surface is just the span of eigenfunctions \( (\psi_1, \psi_2) \), also written as \((x, y)\) in Fig. 4(a). Similarly, if we further consider one of the eigenvectors of \( \mu \) as the third coordinate for respective control vertices over \((x, y)\) in Fig. 4(a), the resulting subdivision surface will be the span of eigenfunctions \((\psi_1, \psi_2, \psi_i)\), \(i = 3, 4, 5\), also written as \((x, y, z)\) in Fig. 4(b), corresponding to one of the three independent eigenvectors of \( \mu \), respectively. We can write \( \psi_i, i = 3, 4, 5, \) as \( z_j, j = 1, 2, 3, \) but for simplicity as \( z_i, i = 1, 2, 3 \) in the rest of the paper, see Fig. 4(b) for the cup case of valence \( N = 7 \).

The quadratic precision error. As \( C^2 \) continuity at extraordinary positions requires eigenfunctions corresponding to \( \mu \) to be standard quadratics of eigenfunctions for \( \lambda \), the condition in Eq. (6) can be rewritten into the following form that can be used for optimization,

\[
Q_i(x, y, z) = \left( \frac{\partial^2}{\partial x^2} z_i - a_i \right)^2 + \left( \frac{\partial^2}{\partial y^2} z_i - b_i \right)^2 + \left( \frac{\partial^2}{\partial z^2} z_i - c_i \right)^2,
\]

where \((x, y, z) = \tilde{B}^T(\tilde{X}, \tilde{Y}, \tilde{Z}_i)\), \( \tilde{B} \) is the column vector of basis functions to parameterize the integral domain \( \Omega \) in Fig. 4 following the method in [Stam 1998], \( \tilde{X}, \tilde{Y} \) are eigenvectors corresponding to \( \lambda, \tilde{Z}_i, i = 1, 2, 3 \) are eigenvectors for \( \mu \), and \( a_i, b_i, c_i \in \mathbb{R} \) for \( i = 1, 2, 3 \) are coefficients of the \( i \)-th standard quadratics that can be obtained
by minimizing respective integrals of $Q_i(x, y)$ for $i = 1, 2, 3$ as,

$$
\min_{(a_i, b_i, c_i)} e_i(a_i, b_i, c_i) = \frac{\iint_{\Omega} Q_i(x, y) \, dx \, dy}{\iint_{\Omega} 1}, \quad (12)
$$

If we consider $(x, y, z)$ as a subdivision surface, the minimization in Eq. (12) gives standard quadratics of $x$ and $y$ that best fit the subdivision surface $(x, y, z)$. The partial derivatives in Eq. (11) can be computed following the chain rule with the help of basis functions in $B$ and invertible Jacobian matrices guaranteed by $C^2$ conditions.

As the eigenstructure analysis is based on a 5-ring configuration, the integral in Eq. (12) should be performed over all 4-ring patches $\Omega$, i.e., the shaded region in Fig. 4(a) with the hole enclosed. In our implementation, we can perform the integral only on the highlighted region $\Omega_0$ in Fig. 4(a) which contains only regular patches for easy evaluation, and the remaining integral on the region enclosed by $\Omega_0$ can be easily computed as the sum geometric sequences which are convergent due to the parameter bounds in Eq. (8).

Fig. 4. Illustration of the integral domain in Eq. (12): (a) the shaded base domain $\Omega_0$ used for numerical quadrature and (b) an eigenfunction for the subsubdominant eigenvalue $\mu$. Due to the scaling nature of the refinement process for eigenvectors, the integral over $\Omega$, i.e., the union of $\Omega_0$ and the hole region enclosed, can often be computed from the integral over $\Omega_0$ as the sum of geometric sequences.

Weighting function to further improve second order characteristic maps. Curvature performances near extraordinary positions are heavily influenced by second order characteristic maps. If second order characteristic maps have sign-changing Gauss curvatures, the resulting limit surface might have hybrid curvature behavior that leads to artifacts [Peters and Reif 2004].

We use a weighting function to penalize sign changes for Gauss curvature on second order characteristic maps. Following the same notations in Eq. (11), Gauss curvature for three second order characteristic maps is computed as [Pressley 2010]

$$
K^i_i(x, y) = \left[ 1 + \left( \frac{\partial z_i}{\partial x} \right)^2 + \left( \frac{\partial z_i}{\partial y} \right)^2 \right]^{2}, \quad i = 1, 2, 3. \quad (13)
$$

As we are mostly interested in the sign of $K^i_i(x, y)$, we only use the numerator of $K^i_i(x, y)$ for subsequent computations, written as

$$
K_i(x, y) = \frac{\partial^2 z_i}{\partial x^2} \frac{\partial^2 z_i}{\partial y^2} - \left( \frac{\partial^2 z_i}{\partial x \partial y} \right)^2. \quad (14)
$$

Ideally, if $C^2$ continuity conditions are satisfied, $K_i(x, y)$ should be a constant equal to $a_i c_i - b_i^2$. For the cup case of the second order characteristic map, $a_i c_i - b_i^2 > 0$, while for the saddle cases, $a_i c_i - b_i^2 < 0$. Now we redefine $K_i(x, y)$ as

$$
K_i(x, y) = \text{sign}(a_i c_i - b_i^2) \left[ \frac{\partial^2 z_i}{\partial x^2} \frac{\partial^2 z_i}{\partial y^2} - \left( \frac{\partial^2 z_i}{\partial x \partial y} \right)^2 \right]. \quad (15)
$$

Through multiplication by the sign of the Gauss curvature for the ideal case, i.e., $\text{sign}(a_i c_i - b_i^2)$, the new form of $K_i(x, y)$ in Eq. (15) will only be negative if Gauss curvature takes signs other than $\text{sign}(a_i c_i - b_i^2)$. We thus only need to penalize the case for $K_i(x, y) < 0$. A regularization operator for $K_i(x, y)$ can be defined as

$$
r(K_i, \epsilon_i) = \frac{K_i(x, y) + \frac{\epsilon_i^2}{r(K_i, \epsilon_i)}}{2}, \quad (16)
$$

where $\epsilon_i$ is the regularization parameter. With lower $\epsilon_i$ values, $r(K_i, \epsilon_i)$ approximates $K_i(x, y)$ better for $K_i(x, y) > 0$, while for $K_i(x, y) < 0$, $r(K_i, \epsilon_i)$ becomes a small positive number that can be used in the denominator as a penalty for $K_i(x, y) < 0$, see Fig. 5(a).

Based on the properties of $r(K_i, \epsilon_i)$, a dimensionless weighting function is thus constructed of the following form

$$
\omega_i(K_i, \epsilon_i, n) = \frac{r(K_i, n \epsilon_i)}{r(K_i, \epsilon_i)}, \quad (17)
$$

where $n$ is a parameter to control the maximum weight applied, and $\epsilon_i$ describes the overall slope for $\omega_i$ near $K_i(x, y) = 0$. The maximum weight is $n^2$ and lower $\epsilon_i$ values produce steeper $\omega_i$ curves, as illustrated in Fig. 5(b).

A penalty will be applied if $K_i(x, y) < 0$ when sign changes appear in Gauss curvatures, and the influence of the weighting function would be negligible for larger $K_i(x, y)$ values, which is desirable for stencil tuning.

Fig. 5. Illustrations for the weighting functions in Eq. (17): (a) the regularization function in Eq. (16) with different regularization parameters $\epsilon_i$, and (b) the weighting functions in Eq. (17) with different $n$ and $\epsilon_i$ values.
The weighted objective function for stencil optimization. In this work, we use the following integral of weighted quadratic precision error to quantify the quality of each map,
\[
E_i(N, \lambda, f_2, f_3) = \frac{\int_\Omega w_i(K_i, \epsilon_i, n)Q_i(x, y) \, dx \, dy}{\int_\Omega dx \, dy}, \quad i = 1, 2, 3, \quad (18)
\]
where \(Q_i(x, y)\) and \(w_i(K_i, \epsilon_i, n)\) are quadratic precision errors and the weighting function in Eq. (11) and Eq. (17), respectively, and the denominator is the area of the integral domain used for normalization.

The optimized stencil coefficients \((f_2, f_3)\) for specified \(\lambda\) of valence \(N\) can be obtained through the following minimization problem,
\[
\left\{ \begin{array}{l}
\min_{(f_2, f_3)} \ E(N, \lambda, f_2, f_3) = \sum_{i=1}^{3} E_i(N, \lambda, f_2, f_3) \\
\text{s.t. } G(N, \lambda, f_2, f_3) \leq 0,
\end{array} \right. \quad (19)
\]
where \(G(N, \lambda, f_2, f_3)\) contains parameter bounds in Eq. (8).
computing the objective function in Eq. (19) are finally produced with $5 \times 5$ Gaussian points for each patch, and detailed procedures for the optimization are illustrated in Algorithm 1.

4.2 Calculation of global optimal stencil coefficients
Apart from stencil coefficients at discrete sample $\lambda$ values, we also compute global optimal subdivision stencils ($\lambda_C^*, f_2, f_3$) over the entire feasible domain for $\lambda$ for each valence $N$, which will be recovered by spline stencils in this work. The optimal $\lambda_C^*$ value for a specified $N$, along with corresponding optimal stencil $f_2$ and $f_3$ values, can be obtained by another layer of one-dimensional optimization with $\lambda$ being the variable for minimization by Eq. (19). The optimization framework in this case is slightly different from Algorithm 1, but similar to that in [Ma and Ma 2018] with a different objective function in this work. As expected for valence $N = 4$, the above optimization in $\lambda$ produces stencils for bi-cubic B-spline subdivision with $f_2 = f_3 = 1/4$ at $\lambda_C^* = 1/2$, i.e., the regular case.

4.3 Spline representation of main stencil coefficients
With optimized stencil coefficients at sample $\lambda$ values, we show in Fig. 6(a) for discrete points, including the global optimal stencil at $\lambda_C^*$ in Section 4.2, we further construct spline representations of $f_2(\lambda)$ and $f_3(\lambda)$ in $\lambda$ through B-spline approximation [Piegl and Tiller 1997].

4.3.1 Determination of knot vectors. We propose to use B-spline functions with degree $p = 3$ and with open knots for representing $f_2$ and $f_3$ against $\lambda$ for all valences $N = 3, \ldots, 20$.

Observed in Fig. 7 that there are feature $\lambda$ values at which the $f_2$ and $f_3$ functions are $C^0$ continuous, mostly caused by parameter bounds. We place $p$-multiple knots at such feature $\lambda$ values. It should be noted that for consistency of knot structures, three $p$-multiple knots, denoted by $\lambda_b, \lambda_c = \lambda_l$, and $\lambda_d$, are assigned for all knot vectors of $N = 3, \ldots, 20$, even though the functions for $f_2$ and $f_3$ are smooth at such $\lambda$ values for some valences $N$. In such cases, the required $p$-multiple knots are inserted by knot insertion after obtaining the desired $f_2$ or $f_3$ functions. Between each pair of multiple knots, an intermediate knot is also inserted to enrich the knot vector for better representation of $f_2$ and $f_3$ functions. The knot vectors for $f_2$ and $f_3$ functions are structured in the form of

$$\Xi = \{\xi_1, \ldots, \xi_{n_p+p+1}\}$$

$$= \left\{\lambda_a, \lambda_b^-, \lambda_b^+, \lambda_c, \lambda_d, \lambda_d^+, \lambda_e \right\},$$

(21)

where $n_p = 17$ is the number of control coefficients for $f_2$ and $f_3$ following the proposed knots structure.

Details for each knot value can be found in Table 1. Knots with superscripts $+$ and $-$ are intermediate knots inserted at the center of neighboring multiple knots.

4.3.2 Calculation of control coefficients for $f_2$ and $f_3$ functions. When constructing the spline stencils, we require resulting $f_2(\lambda)$ and $f_3(\lambda)$ functions to exactly recover the global optimal stencil at $\lambda_C^*$ for all valence $N$, including the regular stencil for $N = 4$ at $\lambda_C^* = 1/2$. Given knots $\Xi$ with degree $p$ defined in Eq. (21) and $m$ optimized discrete stencil parameters of $f_2$ and $f_3$ with respective $\lambda$ values obtained for $\lambda \in [\lambda_a, \lambda_e]$ from the previous subsection, collectively denoted here as $M$, we thus further construct B-spline functions $f_2(\lambda)$ and $f_3(\lambda)$ approximating $M$ with $\Xi$ through constrained B-spline approximation while interpolating the globally optimal stencil at $\lambda_C^*$ for all valences $N$. During the process of approximation, we also apply inequality constraints at all discrete sample stencils in $M$ such that the resulting spline stencils of $f_2(\lambda)$ and $f_3(\lambda)$ would fall within respective upper and lower bounds in Eqs. (53)-(62), see supplementary materials (Section B).
Fig. 7. Stencil coefficients $f_3(\lambda)$ and $f_5(\lambda)$ for selected valences $N \leq 20$. Regions shaded with orange and blue are the feasible domains for $f_2$ and $f_3$, respectively. The recommended regions for $\lambda \in [\lambda_{1}, \lambda_{2}]$ in Section 4.4 are highlighted by a piece of thicker lines in the plots for $f_2$ and $f_3$, and their boundaries are highlighted by black dashed lines. Some other featured $\lambda$ values in Section 4.4 are also marked for reference.

During the approximation process in the implementation, we only apply multiple knots at visually $C^0$ positions, if exist for certain valences $N$, and at the two end knots. We later insert respective multiple knots in the knot vector to recover the knot structure in $\Xi$ afterwards. Also, as indicated in Eqs. (61)-(62) in supplementary materials (Section B), parameter bounds for $f_2$ are influenced by $f_5$, so for each valence $N$, we produce the spline approximation of $f_5$ first followed by the computation of $f_2$ spline function.

The results of spline approximations are control coefficients of $f_5(\lambda)$, $i = 2, 3$ for each of the respective valence $N \leq 20$, that can be organized as a vector $\mathbf{\bar{C}}^N_i$. Combined with knots $\Xi$ with degree $p$, the B-spline representations of $f_i(\lambda)$, $i = 2, 3$ are thus fully defined. Full lists of control coefficients $\mathbf{\bar{C}}^N_i$ for $f_i(\lambda)$, $i = 2, 3$ can be found in Table 5 and Table 6 in supplementary materials (Section C). See also Section 4.5 for further information on the evaluation of $f_i(\lambda)$, $i = 2, 3$ and further construction of desired full subdivision stencils.

4.3.3 Illustration of spline functions of $f_2(\lambda)$ and $f_3(\lambda)$. The obtained spline functions of $f_2(\lambda)$ and $f_3(\lambda)$ for $N = 6$ are illustrated in Fig. 6. From Fig. 6(b) and (d), it can be seen that spline functions $f_2(\lambda)$ and $f_3(\lambda)$ approximate discrete optimized $f_2$ and $f_3$ values well over the entire feasible domain for $\lambda \in [\lambda_0, \lambda_\mathcal{C}]$. The relaxation parameter $s$ in Eq. (10) follows the same pattern of Fig. 6(e) for all valences $N$. The angle $\theta$ is the half-angle of the outermost corner of 1-ring quadrilaterals in the respective natural configurations, and $\theta$ should be $\leq \frac{\pi}{4}$ to avoid concave corners and to ensure regularity and injectivity of characteristic maps for $C^1$ continuity. In this work, we require that $\theta \leq \frac{\pi}{4} - \frac{\pi}{k}$, leading to parameter bounds of Eq. (62) and Eq. (60) in supplementary materials (Section B). The application of $\theta$ constraints in stencil optimization and for regularity check are similar to that in [Ma and Ma 2019a]. Fig. 6(f) illustrates the resulting spline stencil parameters $f_2(\lambda)$, $f_3(\lambda)$, and respective $E(N, \lambda, f_2, f_3)$, with marked parameters at some featured $\lambda$ for valence $N = 6$. Fig. 7 provides further illustrations of $f_2(\lambda)$ and $f_3(\lambda)$ similar to that in Fig. 6(f) for some other selected valences.

4.4 Highlights of featured $\lambda$ values and regions
Properties of the proposed unified $\lambda$-subdivision scheme depend upon the selection of the $\lambda$ value. Table 1 highlights several featured $\lambda$ values that are useful for practical applications.

Table 1. Summary of important and featured $\lambda$ values, see also Fig. 3. Multiple knots used in Eq. (21), i.e., $\lambda_0, \lambda_\mathcal{C} = \lambda_1$, and $\lambda_d$, are shaded with light gray, while $\lambda_\mathcal{C} = 0.15$ and $\lambda_d = 0.9$ are not listed in the table. The column $\lambda_{\mathcal{C}}$ contains $\lambda$ values for Catmull-Clark subdivision for reference.
\[ \lambda_l \text{ is the lower bound for } \lambda \text{ to have bounded curvature. Values of } \lambda_l \text{ can be found in Table 1, and explicit computation for } \lambda_l \text{ can also be found in Eq. (23).} \]

\[ \lambda^* \text{ is the value of } \lambda \text{ with global optimal bounded curvature for any valence } N \text{ over the entire feasible domain for } \lambda. \text{ By using } \lambda = \lambda_C, \text{ the } f_2 \text{ and } f_3 \text{ functions will return subdivision stencils that produce the best possible surface qualities.} \]

\[ \lambda^* = 0.39 \text{ is the value of } \lambda \text{ that produces IGA solutions with optimal convergence rates in } L^2 \text{-norms [Ma and Ma 2019a]. If errors in other norms are considered, such as } H^1 \text{- and } L^\infty \text{-norms, even lower } \lambda \text{ values should be used.} \]

\[ \lambda^* = 1/2 \text{ is the value of } \lambda \text{ that produces uniform refined meshes with the least polar artifacts.} \]

\[ \lambda_{r1} \text{ is an empirical lower bound for the recommended region of } \lambda. \text{ For } \lambda < \lambda_{r1}, \text{ the subdivision schemes are less stable. A slight decrease in } \lambda \text{ might lead to rapid increase of } E(N, \lambda, f_2, f_3) \text{ in Eq. (19), especially for higher valences, see Fig. 7(g) and (h).} \]

\[ \lambda_{r2} \text{ is an empirical upper bound for the recommended region of } \lambda. \text{ For } \lambda > \lambda_{r2}, \text{ the subdivision schemes are also less stable with possible overlapping or concave 2-ring quadrilaterals in respective natural configurations.} \]

In summary, while the feasible region of the resulting spline stencil parameters of } f_2(\lambda) \text{ and } f_3(\lambda) \text{ is } \lambda \in [\lambda_{r1}, \lambda_{r2}], \text{ the recommended region for practical applications is } \lambda \in [\lambda_l, \lambda_C] \text{ for producing quality subdivisions. While the proposed unified } \lambda \text{ subdivision scheme produces bounded curvature subdivisions in theory for } \lambda \in [\lambda_l, \lambda_C] \text{ as shown in Fig. 3, it produces well behaved bounded curvature subdivisions for } \lambda \in [\lambda_l, \lambda_{r2}]. \]

Also note that at } \lambda_C, \lambda_A, \text{ and } \lambda_M, \text{ the proposed unified } \lambda \text{ subdivision scheme produces optimized subdivision stencils having similar properties to that in [Augsdörfer et al. 2006; Ma and Ma 2018] with the best curvature performance, [Ma and Ma 2019a; Wei et al. 2021] at lower } \lambda \text{ values with improved performance in IGA, and [Ma and Ma 2019b; Reif and Sabin 2019] at } \lambda \text{ close to } 1/2 \text{ with uniform refined meshes, respectively.} \]

4.5 Stencil evaluation at given } \lambda \text{ values}

As stencil coefficients } f_2(\lambda) \text{ and } f_3(\lambda) \text{ are represented as } B \text{-spline functions, they can be efficiently evaluated [Piegler and Tiller 1997]. If the column vector } \mathbf{b}(\lambda) \text{ contains } B \text{-spline basis functions corresponding to } \Xi \text{ at } \lambda, \text{ then the } f_2 \text{ and } f_3 \text{ values at } \lambda \text{ for valence } N, \text{ denoted by } f_i(N, \lambda), \ i = 2, 3, \text{ can be written as}

\[ f_i(N, \lambda) = \mathbf{b}^T(\lambda) \mathbf{C}_N^i, \ \lambda \in [\lambda_l, \lambda_C], \text{ for } i = 2, 3, \]

where } \mathbf{C}_N^i \text{ is the vector of control coefficients for } f_i \text{ of valence } N, \ i = 2, 3, \text{ and } \mathbf{C}_N^i \text{ is available in supplementary materials (Section C).} \]

In Table 2 and Table 3 of the attached supplementary materials (Section C), we also include selected evaluations of } f_2(\lambda) \text{ and } f_3(\lambda) \text{ at some featured } \lambda \text{ values that can be readily used for further computing relevant full subdivision stencils.}

With } N, \lambda, f_2, \text{ and } f_3 \text{ given, other stencil parameters or subdivision coefficients can be further computed by simple arithmetic formulæ as follows. First we compute the lower bound } \lambda_l \text{ for bounded curvature. For a specific valence } N, \lambda_l \text{ is given as}

\[ \lambda_l = \begin{cases} \lambda_l^N, & \text{for } N < 5, \\ \max(\lambda_l^N, \lambda_l^3), & \text{for } N \geq 5, \end{cases} \]

where

\[ \lambda_l^1 = \sqrt{\frac{1}{8}}, \quad \lambda_l^3 = \frac{c_{n2}^N}{c_{n1}^N}, \quad \lambda_l^4 = 1 + \frac{c_{n2}^N}{1 + 2c_{n1}^N - c_{n2}^N}, \]

with } c_{n1} = \cos(2\pi/N) \text{ and } c_{n2} = \cos(4\pi/N) \text{. Note that values of } \lambda_l \text{ are also recorded in Table 1, with four decimal places.} \]

Then we compute } s \text{ following Eq. (10), where } \lambda_l \text{ is used. The remaining stencil coefficients can thus be computed as}

\[ f_1 = 1 - 2f_2 - f_3, \quad d_1 = g_1 + 2g_2f_1, \quad d_2 = g_3 + 2g_2f_2, \]

\[ e_1 = g_2f_2, \quad e_2 = g_2f_3, \]

\[ \beta = f_3(2e_1 + d_2) - 4f_2e_2 + \mu^2 - (f_3 + 2e_1 + d_2)\mu \]

\[ \alpha = \varphi_n\beta, \quad \varphi_n = 6 \]

\[ \mu = s\lambda^2, \]

\[ \gamma_1 = s\lambda^2 \left( 1 + c_{n1} \right) s\lambda^2 - (1 + c_{n2})\lambda + f_3(c_{n2} - c_{n1}) \]

\[ (c_{n1} - c_{n2})s\lambda^2 + f_3(1 + c_{n2})s\lambda - f_3(1 + c_{n1}) \]

\[ g_2 = \lambda(\lambda - f_3) + (f_3 - \lambda)g_3 \]

\[ g_1 = 1 - 2g_2 - g_3 \]

The intermediate variables, } g_1, g_2, \text{ and } g_3, \text{ are generalized Catmull-Clark coefficients [Ma and Ma 2018] for refined edge vertices}

\[ V_E = g_1V_0 + g_2(V_F + V'_F) + g_3V_1, \]

where } V_0 \text{ is the original extraordinary vertex, } V_0 \text{ and } V_1 \text{ are end vertices of the corresponding edge in the original mesh, and } V_F \text{ and } V'_F \text{ are two neighboring face vertices in the refined mesh.}

5 EXAMPLES AND FURTHER DISCUSSIONS

5.1 Performance at various } \lambda \text{ values}

Fig. 8 provides illustrations of limit surfaces of two general models with subdivision in extraordinary regions at a range of } \lambda \text{ values using our method. One can observe that, the } \lambda \text{-subdivision scheme produces the most favorable models when } \lambda \text{ falls in the middle region, while minor visual surface twisting might appear when } \lambda \text{ is selected either too small or too large on the two sides. Fig. 9 provides some further illustrations of the proposed method on two other general models at some important featured } \lambda \text{ values, } \lambda_M^*, \text{ and } \lambda_C^*. \text{ The result is consistent with observations in Fig. 8.} \]

In terms of refined mesh structure, the value of } \lambda \text{ directly influences the contraction of 1-ring vertices, which can be seen both in Fig. 10 with selected natural configurations and in Fig. 11(a-e) with refined meshes. The proposed } \lambda \text{-subdivision at } \lambda = \lambda_M^* \text{ for each valence } N \text{ in Table 1 produces the smoothest limit surface as shown in Fig. 9 and Fig. 11, and refined meshes are the most uniform for } \lambda = \lambda_M^* = 0.5, \text{ as shown in Fig. 10(g)(h)(i) and Fig. 11(e).} \]
The proposed \( \lambda \)-subdivision scheme is an improved generalization of existing schemes in [Ma and Ma 2019a], [Ma and Ma 2018], and [Ma and Ma 2019b], with corresponding \( \lambda \) denoted by \( \lambda_A, \lambda_C, \) and \( \lambda_M \). Here we compare the proposed method with these schemes and the classical Catmull-Clark subdivision [Catmull and Clark 1978].

Comparison of second order characteristic maps: Compared with previous schemes [Ma and Ma 2019a], [Ma and Ma 2018], and [Ma and Ma 2019b], a major difference is that we use a weighted objective function in subdivision tuning to penalize the undesired sign changes of second order characteristic maps for producing better surfaces. We use \( K_m \) defined in Eq. (33) to measure the extent of overall sign change for three second order characteristic maps,

\[
K_m = \max(-K_{m_1}, 0) + \max(K_{m_2}, 0) + \max(K_{m_3}, 0). \tag{33}
\]

\( K_{m_1} \) is the minimum Gauss curvature for the cup case which ideally should be positive, and \( K_{m_2} \) and \( K_{m_3} \) are the maximum Gauss curvature for two saddle cases which ideally should be negative. The smaller the \( K_m \) value, the better the respective subdivision with less Gauss curvature sign changes.

The comparison of \( K_m \) between the proposed scheme and [Ma and Ma 2019a] is illustrated in Fig. 13, which shows that the proposed scheme produces better maps with less Gauss curvature sign changes than that in [Ma and Ma 2019a]. The results for comparison among the proposed scheme and three previous schemes [Catmull and Clark 1978], [Ma and Ma 2019b] and [Ma and Ma 2018] are omitted since \( K_m \) vanishes for all of them, which indicate that all these schemes, including ours at higher \( \lambda \) values, produce second order maps with no Gauss curvature sign changes.

Further comparisons on meshes with a single EV: Our method is also compared with [Ma and Ma 2019a] on challenging single-EV meshes in Fig. 12 for further validation of performances at lower \( \lambda \) values. Comparisons with Catmull-Clark subdivision are also included as a baseline, see Fig. 14 and Fig. 15.

At lower \( \lambda \) values, e.g., \( \lambda = \lambda_A \), the proposed method produces tuned subdivisions with better second order maps and better limit surfaces than [Ma and Ma 2019a], as illustrated in Fig. 14(a-f) and Fig. 15(a-f). The ridges in surface renderings are alleviated, and the highlight lines are smoother for our method. Gauss curvatures by our method have tighter bounds and are more uniformly distributed. By using the same \( \lambda \) value of Catmull-Clark subdivision, our scheme generates surfaces with smoother highlight lines and bounded Gauss curvature, see comparisons in Fig. 14(g-l) and Fig. 15(g-l).

For tuned subdivisions at \( \lambda \) values in the middle region, as the influence of weighting function in Eq. (17) is limited, the proposed method produces almost identical results at \( \lambda_M^{+} \) and \( \lambda_C^{+} \), compared with tuned subdivisions in [Ma and Ma 2019b] and [Ma and Ma 2018], respectively, and relevant comparisons are thus omitted.

5.3 Other observations and further discussions

The proposed \( \lambda \)-subdivision scheme produces tuned subdivisions and further generalization of Catmull-Clark subdivision. All existing schemes for sharp features for Catmull-Clark subdivision can be directly integrated into our scheme. From Fig. 8 at \( \lambda = 0.3, 0.5, 0.7 \), we also observe
that soft crease features appear on limit surfaces in extraordinary regions with lower \( \lambda \) values. This property could be further addressed to develop an alternative scheme for defining soft or semi-sharp features over \( \lambda \)-subdivision surfaces. Properly organized subdivisions with a lower \( \lambda \) value can be applied at tagged vertices/edges with which newly inserted vertices can be positioned close to the respective crease edge forming a soft crease. Sharpness of the soft crease can be controlled by \( \lambda \).

The proposed \( \lambda \)-subdivision scheme could also be used for mesh reparameterization with desired distribution of control vertices for producing field-aligned solutions in isogeometric analysis. For fluid flow simulation or crack animation, for example, one can perform mesh refinement or develop mesh reparameterization algorithms using \( \lambda \)-subdivision rules to increase mesh density near crack or at other desired positions for producing solutions with reduced local errors and balanced solution error distribution.

Fig. 9. Results from the proposed scheme on general meshes at selected \( \lambda \): (a-b) initial control meshes of “Kitten” (from Jakob et al. 2015) with EVs of \( N = 3, 5, 6 \) and “Propeller” (from Scott et al. 2013) with EVs of \( N = 3, 5 \); (c-h) results for “Kitten”; and (i-n) results for “Propeller”. Results for \( \lambda = \lambda^*_A \), \( \lambda^*_M \) and \( \lambda^*_C \) are illustrated in columns 1 to 3, respectively. The highlighted regions illustrate highlight lines near EVs of valence \( N = 5 \).

Fig. 10. Natural configurations at selected \( \lambda \) values for \( N = 5, 8, 11 \) in columns 1 to 3, respectively. Note that respective maps are organized following an ascending order from the first row to the fifth row. Featured \( \lambda \) values can be found in Table 1.
An Unified $\lambda$-subdivision Scheme for Quadrilateral Meshes with Optimal Curvature Performance in Extraordinary Regions

Fig. 11. Illustration of results for the $N = 7$ mesh at featured $\lambda$ values: (a-e) meshes after two steps of subdivision; (f-j) rendering of limit surfaces; (k-o) Gauss curvature distributions; and (p-t) highlight lines. Results for $\lambda = 0.35$, $\lambda^*_A$, $\lambda^*_M$, $\lambda^*_C$, and $\lambda^*_C + \lambda$ with $\Delta \lambda = (\lambda^*_C - \lambda^*_C) / 2$, are illustrated in columns 1 to 5, respectively. Gauss curvature is denoted by $K_G$, and the same color scale is used for all Gauss curvature plottings.

Fig. 12. Three challenging meshes from [Karčiauskas and Peters [n. d.]] with a single extraordinary vertex for comparisons: (a) $N = 5$; (b) $N = 6$; and (c) $N = 7$. Note that the $N = 6$ mesh is convex while the other two are saddle meshes.

6 CONCLUSIONS AND FUTURE WORK
In this paper, we propose a continuous family of subdivision schemes that generalizes several existing tuned schemes. The main subdivision coefficients in this work are represented as B-spline functions of subdominant eigenvalues $\lambda$. Tedious stencil tuning is avoided for potential users, and the evaluation of subdivision stencils at given $\lambda$ values can be performed by B-spline evaluations followed by simple arithmetic calculations. A tuning framework has been proposed for subdivision stencil optimization towards curvature continuity conditions. The bounded curvature constraint has been relaxed for extended feasible domains of $\lambda$ with minimum possible curvature.

ACM Trans. Graph., Vol. 42, No. 6, Article 209. Publication date: December 2023.
values. Optimized stencils are then reforged into B-spline representations for easy evaluation. Properties of the proposed scheme at different $\lambda$ values have been validated by numerical examples. The improvement of surface qualities at lower $\lambda$ values have also been verified. The proposed unified $\lambda$-subdivision scheme can be applied in both graphics and engineering analysis. As future works, we will apply the proposed method for the creation of semi-sharp features, and use the method to solve relevant engineering problems.
