Abstract. The formation of secondary organic aerosol (SOA) has been widely studied in the presence of dry seed particles at low relative humidity (RH). At higher RH, initially dry seed particles can exist as wet particles due to water uptake by the seeds as well as the SOA. Here, we investigated the formation of SOA from the photooxidation of toluene using an oxidation flow reactor in the absence of NOx under a range of OH exposures on initially wet or dry ammonium sulfate (AS) seed particles at an RH of 68 %. The ratio of the SOA yield on wet AS seeds to that on dry AS seeds, the relative SOA yield, decreased from 1.31 ± 0.02 at an OH exposure of 4.66 × 10¹⁰ molecules cm⁻³ s to 1.01 ± 0.01 at an OH exposure of 5.28 × 10¹¹ molecules cm⁻³ s. This decrease may be due to the early deliquescence of initially dry AS seeds after being coated by highly oxidized toluene-derived SOA. SOA formation lowered the deliquescence RH of AS and resulted in the uptake of water by both AS and SOA. Hence the initially dry AS seeds contained aerosol liquid water (ALW) soon after SOA formation, and the SOA yield and ALW approached those of the initially wet AS seeds as OH exposure and ALW increased, especially at high OH exposure. However, a higher oxidation state of the SOA on initially wet AS seeds than that on dry AS seeds was observed at all levels of OH exposure. The difference in mass fractions of m/z 29, 43 and 44 of SOA mass spectra, obtained using an aerosol mass spectrometer (AMS), indicated that SOA formed on initially wet seeds may be enriched in earlier-generation products containing carbonyl functional groups at low OH exposures and later-generation products containing acidic functional groups at high exposures. Our results suggest that inorganic dry seeds become at least partially deliquesced particles during SOA formation and hence that ALW is inevitably involved in the SOA formation at moderate RH. More laboratory experiments conducted with a wide variety of SOA precursors and inorganic seeds under different NOx and RH conditions are warranted.

1 Introduction

Secondary organic aerosol (SOA) is an important component of atmospheric particulate matter, which influences air quality, climate and human health (Hallquist et al., 2009). SOA is mainly formed via the oxidation of volatile organic compounds (VOCs), followed by partitioning to the condensed phase. Traditional atmospheric chemical transport models largely underestimate the levels of SOA (de Gouw et al., 2005; Volkamer et al., 2006; Hodzic et al., 2010) and the degree of oxidation (Rudich et al., 2007; Ng et al., 2010). The updated models incorporating the volatility basis set (VBS) formalism (Donahue et al., 2006) can better predict the observed SOA, but SOA formation still remains under-constrained (Shrivastava et al., 2011; Tsigaridis et al., 2014; Hayes et al., 2015; Ma et al., 2017). SOA yields in atmospheric chemical transport models are obtained from smog chamber experiments using dry seed particles (Barsanti et
yet atmospheric relative humidity (RH) is often sufficiently high that aerosols often contain aerosol liquid water (ALW) due to their hygroscopic properties (Liao and Seinfeld, 2005; Lee and Adams, 2010; Guo et al., 2015; Nguyen et al., 2016). The presence of ALW in aerosols may enhance SOA formation by facilitating the partitioning of semivolatile organic compounds (SVOCs) and the uptake of water-soluble gases through aqueous-phase reactions (Hennigan et al., 2008; Lim et al., 2010; Ervens et al., 2011; Lee et al., 2011; Sareen et al., 2017). ALW may also promote photodegradation of dissolved SOA (Romonsky et al., 2015). Therefore, SOA formation under atmospherically relevant relative humidity needs to be better constrained in atmospheric chemical transport models by incorporating ALW. In addition, understanding water uptake of SOA is important for estimating its loss by wet deposition, which is not well constrained.

Aromatic hydrocarbons constitute a large fraction of the total non-methane hydrocarbons in the urban atmosphere (Calvert et al., 2002) and account for a significant fraction of SOA in urban areas (Ding et al., 2012; Zhao et al., 2017). Toluene is the most abundant aromatic hydrocarbon (Calvert et al., 2002; Zhang et al., 2016), and SOA yields from the photooxidation of toluene on dry or wet ammonium sulfate (AS) seeds have been studied by varying the RH in smog chambers. Kamens et al. (2011) observed higher yields of SOA from toluene at higher RHs. They attributed this increase to the initially wet seed particles. On the other hand, Edney et al. (2000) reported that wet seeds had no effect on the SOA yields of toluene compared with dry seeds. In these studies, different RHs used for dry- and wet-seed experiments may influence the gas-phase chemistry and complicate the comparison of SOA formation.

SOA formation on initially dry and wet AS seeds has been compared using oxidation flow reactors at the same RHs (Wong et al., 2015; Faust et al., 2017). Faust et al. (2017) found a 19% enhancement in the SOA yield of toluene on wet AS seeds over that on dry AS seeds at 70% RH. However, at such high RH, the initially dry and water-free AS seed particles can uptake water upon SOA formation because SOA themselves can be hygroscopic, and they can also lower the deliquescence RH of the AS seeds (Takahama et al., 2007; Smith et al., 2011, 2012, 2013). The potential influence of SOA formation on the physical state of the initially dry seeds as well as on the overall water uptake by the aged particles was not explicitly discussed. In addition, the hydroxyl radical (OH) exposure in Faust et al. (2017) was approximately $2 \times 10^{11}$ molecules cm$^{-3}$ s, equivalent to about 1.5 days of oxidation in the atmosphere assuming an ambient OH concentration of $1.5 \times 10^6$ molecules cm$^{-3}$ (Mao et al., 2009). Atmospheric particles can undergo oxidation for as long as 1–2 weeks (Balkanski et al., 1993).

In this study, SOA formation from the photooxidation of toluene was investigated in an oxidation flow reactor at an RH of 68% under a wide range of OH exposures using initially wet or dry AS seed particles. The yields and composition of SOA as well as the estimated ALW contents for the initially wet and dry seeds are compared. We found that, as OH exposure increased, the SOA yield and ALW of the initially dry seeds approached those of the initially wet seeds, while the wet seeds yielded SOA of a higher degree of oxidation than the dry seeds did at all exposure levels.

### 2 Materials and methods

#### 2.1 Generation of seed particles

A schematic of the experimental setup, similar to that used in Wong et al. (2015) and Faust et al. (2017), is shown in Fig. 1. AS seed particles were generated from an aqueous AS solution (Sigma-Aldrich) using an atomizer (TSI 3076, TSI Inc., USA). In experiments using dry seeds, the atomized aqueous AS droplets passed through a silica gel diffusion dryer so that the phase of the seed particles could be altered or bypassed the diffusion dryer. Either wet or dry AS served as seed particles for the experiments.
When atomizing a given AS solution, the diameter of wet AS droplets is much larger than that of dry AS particles due to the water uptake of AS (Chan et al., 1992), resulting in a larger surface area of seed particles. Previous studies have demonstrated that a large surface area of seed particles may increase the SOA yields by reducing the wall loss of organic vapors (Matsunaga and Ziemann, 2010; Zhang et al., 2014, 2015; Huang et al., 2016; Krechmer et al., 2016). To obtain seed particles of comparable surface areas, we atomized 0.013 and 0.015 mM of the AS solution for wet and dry AS seeds, respectively. As shown in Fig. S1 in the Supplement, the surface area distribution of initially wet AS seeds was similar to that of initially dry AS seeds. Because of the difference in AS concentration between the stock solutions used, wet AS seeds had a mean diameter of 88 nm and were slightly smaller than dry AS seeds, which had a mean diameter of 102 nm. The total surface area of wet AS seeds was 21 % larger than that of dry AS seeds. The mass loading of wet and dry AS seeds was 31.0 and 24.2 µg m$^{-3}$, respectively.

### 2.2 Oxidation flow reactor

SOA formation from the photooxidation of toluene in the absence of NO$_x$ on initially dry or wet seeds was investigated in a potential aerosol mass (PAM) oxidation flow reactor, which has been described in detail elsewhere (Kang et al., 2007, 2011; Lambe et al., 2011a, 2015; Liu et al., 2017). Briefly, a PAM chamber is a continuous oxidation flow reactor using high and controlled levels of oxidants to oxidize gaseous precursors to produce SOA. The chamber used in this study had a volume of approximately 19 L (length: 60 cm; diameter: 20 cm). The total flow rate in the PAM chamber was set at 3 L min$^{-1}$ using mass flow controllers, resulting in a residence time of approximately 380 s. The RH and temperature of the PAM outflow were measured continuously (HMP 110, Vaisala Inc, Finland) and stabilized at approximately 68 % and 20°C, respectively. High OH exposures were realized through the photolysis of ozone irradiated by a UV lamp ($\lambda = 254$ nm) in the presence of water vapor. Ozone was produced by an ozone generator (1000BT-12, ENALY, Japan) via the irradiation of pure O$_2$. The OH concentration was adjusted by varying the concentration of ozone in the PAM chamber from 0.4 to 4.3 ppm. The corresponding upper limit of OH exposure at these operating conditions ranged from 0.47 × 10$^{11}$ to 5.28 × 10$^{11}$ molecules cm$^{-3}$ s$^{-1}$, equivalent to 0.36 to 4.08 days of atmospheric oxidation assuming an ambient OH concentration of 1.5 × 10$^6$ molecules cm$^{-3}$ s$^{-1}$ (Mao et al., 2009). The upper limit of OH exposure was determined by measuring the decay of SO$_2$ (Model T100, TAPI Inc., USA) in the absence of toluene, following procedures described elsewhere (Kang et al., 2007; Lambe et al., 2011a). The reduction in OH exposure due to the addition of toluene was estimated to range from 15 % at the highest OH exposure to 25 % at the lowest OH exposure, using the method of Peng et al. (2016). Peng et al. (2016) found that non-OH chemistry – including photolysis at $\lambda = 254$ nm and reactions with O($^1$D), O($^3$P) and O$_3$ – may play an important role in oxidation flow reactors. In this study, the PAM reactor was operated at water vapor mixing ratios above 0.5 % and external OH reactivity below 20 s$^{-1}$. Non-OH chemistry is expected to play a negligible role under these conditions (Peng et al., 2016).

Before and after each experiment, the PAM reactor was cleaned under an OH exposure of $\sim 1 \times 10^{12}$ molecules cm$^{-3}$ s$^{-1}$ until the mass concentration of background particles dropped below 3 µg m$^{-3}$. After characterizing dry or wet AS seed particles for half an hour, the UV lamp was turned on to oxidize the background gases at five different OH levels to measure the concentrations of background organics. A toluene mixture (29.6 ppm in nitrogen) with a flow rate of 0.013 L min$^{-1}$ was then introduced to initiate SOA formation. The initial concentration of toluene in the PAM reactor was approximately 138 ppb. The reacted and final concentrations of toluene were calculated from the OH exposure and the rate constant of the reaction between toluene and OH (Atkinson and Arey, 2003) (Table 1). The flow and light conditions were the same for initially wet and dry seeds. Therefore, the quantification of toluene would not introduce uncertainties to the relative SOA yields described in Sect. 3.1 as the initial concentrations of toluene and OH exposures were the same for both cases. SOA was measured for at least an hour with a stepwise increase in the five OH levels.

### 2.3 Characterization of non-refractory components

The AS–SOA mixed particles were characterized for the chemical composition of non-refractory components including organics, sulfate and ammonium as well as the elemental ratios of organics using a high-resolution time-of-flight aerosol mass spectrometer (hereafter AMS, Aerodyne Research Incorporated, USA) (DeCarlo et al., 2006). The instrument was operated in the high-sensitivity V mode and the high-resolution W mode, alternating every 1 min. The toolkits Squirrel 1.571 and Pika 1.16I were used to analyze the AMS data. The molar ratios of hydrogen to carbon (H : C) and oxygen to carbon (O : C) were determined using the Aiken method (Aiken et al., 2007, 2008). The ionization efficiency of the AMS was calibrated using 300 nm ammonium nitrate particles. The particle-free matrix air, obtained by passing the airflow from the PAM reactor through a HEPA filter, was measured for at least 20 min before each experiment to determine the signals from major gases.

The collection efficiency (CE) of an AMS is dependent on the chemical composition and acidity as well as the phase state of particles (Matthew et al., 2008; Middlebrook et al., 2012). Matthew et al. (2008) found that the CE for solid particles thickly coated with liquid organics was 100 %. In this study, experiments were conducted at an RH of 68 %, exceeding the RH threshold for the semisolid-to-liquid phase.
transition for toluene-derived SOA (Bateman et al., 2015; Song et al., 2016). The toluene-derived SOA in these experiments was therefore liquid-like. The unimodal size distributions of particle numbers show the SOA formation on AS seed particles without many nucleation mode particles (Fig. S2). A CE of 1 was used for processing all AMS data since the AS seed particles were coated by liquid SOA. The adoption of this CE value was supported by the fact that the concentration of sulfate measured with the AMS varied by less than 5% of the average mass of sulfate after being coated by SOA for both wet and dry AS seeds conditions. For the quantification of SOA, the contribution from background organic aerosols was subtracted from the total organic aerosols. The ratio of SOA mass to background organic mass ranged from 7 to 59, indicating that the contribution from background organics was negligible. Aerosol particles typically pass through a silica gel diffusion dryer to remove ALW before they are measured by AMS. However, this may lead to some losses of semivolatile organics through reversible partitioning (Wong et al., 2015; Faust et al., 2017). In this study, the AS–SOA mixed-particle stream passed through and bypassed a diffusion dryer alternately before they were measured by AMS. Overall less than 8% of SOA was lost for wet and dry AS seeds after passing the diffusion dryer (Fig. S3), possibly due to reversible partitioning of the SVOCs. In this paper, the data reported are those bypassing the diffusion dryer.

A scanning mobility particle sizer (SMPS, TSI Incorporated, USA, classifier model 3082, CPC model 3775) was used to measure particle number concentrations and size distributions. Particle size ranged from 15 to 661 nm.

To evaluate the influence of seed surface area on SOA formation, we conducted another experiment at OH exposure of $10^{11}$ molecules cm$^{-3}$ s with 50% of the seed surface area used in the wet AS experiment. The difference in SOA concentration was approximately 1% between these two experiments. Hence the 20% difference in seed surface area between wet and dry AS particles cannot account for the difference in SOA yield to be discussed below.

#### 2.4 Estimation of ALW content

The ALW content of the initially dry AS was zero. However, as reactions proceed, SOA themselves can uptake water and also lower the deliquescence RH of AS, leading to water uptake by AS and some fractions of AS in the aqueous phase. The ALW contents of AS ($\text{ALW}_{\text{AS}}$) and toluene-derived SOA ($\text{ALW}_{\text{SOA}}$) were estimated from the following equations (Kreidenweis et al., 2008):

\[
\text{ALW}_{\text{AS}} = V_{\text{AS}} \kappa_{\text{AS}} f \frac{\alpha_w}{1 - \alpha_w} \rho_w, \quad (1)
\]

\[
\text{ALW}_{\text{SOA}} = V_{\text{SOA}} \kappa_{\text{SOA}} \frac{\alpha_w}{1 - \alpha_w} \rho_w, \quad (2)
\]

where $V_{\text{AS}}$ and $V_{\text{SOA}}$ represent the volume concentrations of dry AS and SOA particles, $\kappa_{\text{AS}}$ is the hygroscopicity parameter of AS particles obtained from Kreidenweis et al. (2008), $\kappa_{\text{SOA}}$ is the hygroscopicity parameter of toluene-derived SOA calculated using the linear correlation between $\kappa_{\text{SOA}}$ and the O:C ratios of SOA proposed by Lambe et al. (2011b), the term $f$ is the fraction of AS particles that dissolved, $\alpha_w$ is the water activity and $\rho_w$ is the density of water (1.0 g cm$^{-3}$). Here, $\alpha_w$ was assumed to be equivalent to RH/100 for simplicity. The volume concentrations of dry AS and SOA particles were estimated from the measured mass concentration of AS and SOA assuming their respective particle densities to be 1.77 and 1.4 g cm$^{-3}$ (Ng et al., 2007).

For the initially wet AS seeds, all AS particles were completely aqueous and therefore $f = 1$. For the initially dry AS seeds, before reactions, the AS particles were completely dry and $f = 0$. After reactions, the AS particles became partially or entirely deliquesced upon the formation of toluene-derived SOA. The dissolved fraction of AS particles was regulated by the liquidus curve of the deliquescence relative humidity (DRH($\varepsilon$)) of AS particles coated with toluene-derived SOA (Smith et al., 2013):

\[
f = \begin{cases} 
\varepsilon (1 - \varepsilon_D) & \text{for } \varepsilon < \varepsilon_D \\
\varepsilon_D (1 - \varepsilon) & \text{for } \varepsilon \geq \varepsilon_D
\end{cases}
\]
3 Results and discussion

3.1 SOA yields

Figure 2a shows SOA yields from the photooxidation of toluene on initially wet and dry AS seed particles as a function of OH exposure. The SOA yield was calculated as the SOA mass divided by the mass of reacted toluene. The uncertainty in the SOA yields simply reflected the standard derivation when averaging the SOA mass. In both cases, SOA yields first exhibited an increase, followed by a decrease as the level of OH exposure increased. This trend may be due to the transition of functionalization reactions to fragmentation ones (Kroll et al., 2009; Lambe et al., 2011a). Previous oxidation flow reactor studies suggest that gas-phase chemistry dominates over heterogeneous OH oxidation at OH levels below $1.0 \times 10^{12}$ molecules cm$^{-3}$s (Ortega et al., 2016; Palm et al., 2016). In this study, the highest OH exposure was $5.28 \times 10^{11}$ molecules cm$^{-3}$s, and heterogeneous oxidation of SOA may not play an important role in reducing the mass of SOA, although we cannot exclude that it plays a role. In addition, glyoxal is an important oxidation product of toluene (Kamens et al., 2011). The reactive uptake of glyoxal has been demonstrated to enhance rather than reduce the SOA mass (Liggio et al., 2005a). The SOA yields for dry and wet AS seeds were 0.18–0.31 and 0.22–0.36, respectively, significantly higher than the value of 0.0059 observed in an oxidation flow reactor under comparable conditions (Faust et al., 2017) and the value of 0.09 obtained in another PAM chamber at 30 % RH in the absence of seed particles (Kang et al., 2007). Faust et al. (2017) attributed their significantly lower yields than typical literature values of 0.09–0.30 to the wall loss of particles and the fragmentation of organics in their flow reactor. On the other hand, the SOA yields we obtained are lower than the values of 0.30–0.37 from smog chamber experiments conducted at a similar temperature, SOA mass loading and OH exposure but a lower RH with dry AS seeds (Ng et al., 2007). Note that the wall loss of particles was not corrected in this study, so the SOA yields may be underestimated. As wet and dry AS seeds in this study had similar particle number size distributions, the wall loss of particles would not affect the comparison of SOA yield between wet and dry AS seeds.

As shown in Fig. 2a, a higher SOA yield was observed for wet AS seeds than for dry AS seeds at the same OH exposure, and the difference in SOA yield decreased as the OH exposure increased. The ratio of SOA yields on wet AS seeds to those on dry AS seeds, the relative SOA yield, was 1.31 ± 0.02 at an OH exposure of $0.47 \times 10^{11}$ molecules cm$^{-3}$s but decreased to 1.01 ± 0.01 when the OH exposure was increased to $5.28 \times 10^{11}$ molecules cm$^{-3}$s (Fig. 2b). These ratios are comparable to the 1.19 ± 0.05 observed by Faust et al. (2017) at an OH exposure of approximately $2.0 \times 10^{11}$ molecules cm$^{-3}$s.

The formation of SOA on initially dry AS particles may alter the deliquescence relative humidity (DRH) of AS particles. Smith et al. (2013) found that, when AS particles were coated with toluene-derived SOA, the DRH decreased from 80 to 58 % as the organic volume fraction increased from 0 to 0.8. Therefore, coating AS particles with toluene-derived SOA can change the physical state of initially dry AS seeds and increase the content of ALW$_{AS, dry}$. As shown in Fig. 3a, after reactions, the mass concentration of ALW$_{tot} = $ ALW$_{SOA} + $ ALW$_{AS}$ increased for both wet and dry seeds as the OH exposure increased. The uncertainties for ALW$_{SOA}$ and ALW$_{AS}$ were 22 % and less than 3 %, respectively. They reflect the uncertainties in $\kappa$ and volume concentrations of AS and SOA. The increase in ALW$_{tot, dry}$ was due to the increase in ALW$_{SOA, dry}$, while the increase in ALW$_{tot, wet}$ was driven by the increase in ALW$_{AS, dry}$ at lower OH exposure and by ALW$_{SOA, dry}$ at higher OH exposures. At OH exposure of $0.47 \times 10^{11}$ molecules cm$^{-3}$s, ALW$_{AS, dry}$ increased from 0 to 6.2 µg m$^{-3}$ after reactions due to the partial deliquescence.
exposure of 0.47×10^{11} \text{ molecules cm}^{-3} \text{s} of glyoxal in the particle phase for initially wet AS seeds. If the particle-phase concentration of glyoxal was assumed to be 0 for initially dry AS seeds, the enhanced partitioning of glyoxal alone would account for 24.5% of the mass difference of SOA. Note that other hydrophilic products were not included in this calculation. This analysis suggests that the enhanced partitioning of hydrophilic products may play an important role in the difference of SOA yields at low OH exposures. As discussed above, the initially dry AS seeds approached wet seeds and reduced the differences between wet and dry SOA yields at high OH exposures.

### 3.2 Chemical composition of SOA

Figure 4 shows the high-resolution mass spectra of SOA for initially wet and dry AS seeds at OH exposures of 0.47×10^{11} and 5.28×10^{11} \text{ molecules cm}^{-3} \text{s}. For both types of AS seeds, at an OH exposure of 0.47×10^{11} \text{ molecules cm}^{-3} \text{s}, the most prominent peaks were \textit{m/z} 29 and 43, followed by \textit{m/z} 28 and 44. \textit{m/z} 29 was dominated by ion \textit{CHO}^+, a tracer for alcohols and aldehydes (Lee et al., 2012). The \textit{m/z} 28 and 44 signals, respectively dominated by \textit{CO}^+ and \textit{CO}_2^+, are tracers for organic acids (Ng et al., 2010). At the OH exposure of 5.28×10^{11} \text{ molecules cm}^{-3} \text{s}, the dominant peaks were \textit{m/z} 8 and 44, followed by \textit{m/z} 29 and 43. The increase in mass fractions of the oxygen-containing ions in the SOA mass spectra at a relatively high OH exposure suggests the formation of more oxidized organic aerosols. On the basis of the mass fraction of ions, Fig. S4 shows that, as OH exposure increased, the difference (wet minus dry) in the spectra of toluene-derived SOA changed from positive in \textit{m/z} 29 (\textit{CHO}^+) and \textit{m/z} 43 (\textit{C}_2\text{H}_5\text{O}^+) to \textit{m/z} 28 (\textit{CO}^+) and \textit{m/z} 44 (\textit{CO}_2^+). The increase in OH exposure resulted in a change from more alcohols or aldehydes to more organic acids in the wet-seeded case when compared to the dry-seeded case.

Fragments derived from the AMS data have been extensively used to infer the bulk compositions and evolution of organic aerosols (Zhang et al., 2005; Ng et al., 2010; Heald et al., 2010). Here we used the approach of Ng et al. (2010) and plotted the fractions of the total organic signal at \textit{m/z} 43 (\textit{f}_{43}) vs. \textit{m/z} 44 (\textit{f}_{44}) as well as the triangle based on the analysis of ambient AMS data (Fig. 5). Ng et al. (2010) proposed that aging would cause \textit{f}_{43} and \textit{f}_{44} to converge toward the triangle apex (\textit{f}_{43} = 0.02, \textit{f}_{44} = 0.30). For both wet and dry AS seeds, \textit{f}_{43} first increased and then decreased with the increase of OH exposure, while \textit{f}_{44} increased all the time. This reversing trend of \textit{f}_{43} was the result of the increase and subsequent decrease in \textit{C}_2\text{H}_5\text{O}^+ (Fig. 5), an indicator of products containing carbonyl functional groups. The \textit{f}_{43}/\textit{f}_{44} plot supports our earlier assertion that, as OH exposure increased, the reaction products changed from an earlier-generation dominated by products containing carbonyl func-

![Figure 3](image-url)  
**Figure 3.** Mass concentration of ALW uptake by AS and toluene-derived SOA before (initial) and after reactions (final) for both initially wet and dry AS seeds. Adjoining bars for initially wet and dry seeds have same OH exposures.

\[ (f = 0.43) \text{ of the originally dry AS particles after SOA formation. The difference in ALW}_{\text{AS, dry}} \text{ and ALW}_{\text{AS, wet}} \text{ narrowed, and the ALW}_{\text{total}} \text{ of initially dry AS seeds partially resembled those of the wet ones. At OH exposure between 1.66 \times 10^{11} \text{ and } 5.28 \times 10^{11} \text{ molecules cm}^{-3} \text{s}, the total final organic volume fraction increased to approximately 0.8, and the initially dry AS particles entirely deliquesced after reactions. Based on the reported SOA yield, initial toluene concentration, OH exposure and assumed concentrations of AS seeds (\sim 10–40 \mu g m^{-3}) in Faust et al. (2017), we estimated that an upper limit of 48% of the initially dry AS seeds deliquesced in their study. Similar to this study, SOA coatings on seed particles may change the physical state of initially dry seeds and lower the difference of SOA yields between initially dry- and wet-seed experiments.}

The hydrophilic products can partition more readily into initially wet AS seeds than dry seeds and partially account for the difference in SOA yields. For example, as one of the important oxidation products, glyoxal was estimated to have an effective Henry’s law constant of 4.52 \times 10^8 \text{ m atm}^{-1} \text{ for our initially wet AS seeds due to the “salting-in” effect (Kampf et al., 2013), approximately 3 orders of magnitude higher than that in pure water (Ip et al., 2009). The uptake rate constant of glyoxal can be calculated as (\gamma \nu A)/4, where \gamma is the uptake coefficient, \nu is the gas-phase velocity of glyoxal and A is the total surface area of AS seeds. The uptake rate constant is 4.5 \times 10^{-4} \text{ s}^{-1} for initially wet seeds with \gamma = 2.4 \times 10^{-3} estimated from glyoxal uptake in AS seeds at 68% RH (Liggio et al., 2005b). The average gas-phase glyoxal concentration was modeled to be 4.3 ppb at OH exposure of 0.47 \times 10^{11} \text{ molecules cm}^{-3} \text{s using the Master Chemical Mechanism v 3.3.1 (Jenkin et al., 2003; Bloss et al., 2005}), which would result in approximately 1.6 \mu g m^{-3} of glyoxal in the particle phase for initially wet AS seeds. If the particle-phase concentration of glyoxal was assumed to be 0 for initially dry AS seeds, the enhanced partitioning of glyoxal alone would account for 24.5% of the mass difference of SOA. Note that other hydrophilic products were not included in this calculation. This analysis suggests that the enhanced partitioning of hydrophilic products may play an important role in the difference of SOA yields at low OH exposures. As discussed above, the initially dry AS seeds approached wet seeds and reduced the differences between wet and dry SOA yields at high OH exposures.

**3.2 Chemical composition of SOA**

Figure 4 shows the high-resolution mass spectra of SOA for initially wet and dry AS seeds at OH exposures of 0.47 \times 10^{11} and 5.28 \times 10^{11} \text{ molecules cm}^{-3} \text{s}. For both types of AS seeds, at an OH exposure of 0.47 \times 10^{11} \text{ molecules cm}^{-3} \text{s}, the most prominent peaks were \textit{m/z} 29 and 43, followed by \textit{m/z} 28 and 44. \textit{m/z} 29 was dominated by ion \textit{CHO}^+, a tracer for alcohols and aldehydes (Lee et al., 2012). The \textit{m/z} 28 and 44 signals, respectively dominated by \textit{CO}^+ and \textit{CO}_2^+, are tracers for organic acids (Ng et al., 2010). At the OH exposure of 5.28 \times 10^{11} \text{ molecules cm}^{-3} \text{s}, the dominant peaks were \textit{m/z} 8 and 44, followed by \textit{m/z} 29 and 43. The increase in mass fractions of the oxygen-containing ions in the SOA mass spectra at a relatively high OH exposure suggests the formation of more oxidized organic aerosols. On the basis of the mass fraction of ions, Fig. S4 shows that, as OH exposure increased, the difference (wet minus dry) in the spectra of toluene-derived SOA changed from positive in \textit{m/z} 29 (\textit{CHO}^+) and \textit{m/z} 43 (\textit{C}_2\text{H}_5\text{O}^+) to \textit{m/z} 28 (\textit{CO}^+) and \textit{m/z} 44 (\textit{CO}_2^+). The increase in OH exposure resulted in a change from more alcohols or aldehydes to more organic acids in the wet-seeded case when compared to the dry-seeded case.

Fragments derived from the AMS data have been extensively used to infer the bulk compositions and evolution of organic aerosols (Zhang et al., 2005; Ng et al., 2010; Heald et al., 2010). Here we used the approach of Ng et al. (2010) and plotted the fractions of the total organic signal at \textit{m/z} 43 (\textit{f}_{43}) vs. \textit{m/z} 44 (\textit{f}_{44}) as well as the triangle based on the analysis of ambient AMS data (Fig. 5). Ng et al. (2010) proposed that aging would cause \textit{f}_{43} and \textit{f}_{44} to converge toward the triangle apex (\textit{f}_{43} = 0.02, \textit{f}_{44} = 0.30). For both wet and dry AS seeds, \textit{f}_{43} first increased and then decreased with the increase of OH exposure, while \textit{f}_{44} increased all the time. This reversing trend of \textit{f}_{43} was the result of the increase and subsequent decrease in \textit{C}_2\text{H}_5\text{O}^+ (Fig. 5), an indicator of products containing carbonyl functional groups. The \textit{f}_{43}/\textit{f}_{44} plot supports our earlier assertion that, as OH exposure increased, the reaction products changed from an earlier-generation dominated by products containing carbonyl func-

Figure 6 shows the changes in H:C and O:C ratios as a function of OH exposure in a Van Krevelen diagram (Heald et al., 2010). The standard deviations for H:C and O:C values, determined for the steady-state periods, were all less than 0.01. The O:C ratios for dry and wet AS seeds were in the ranges of 0.59–0.89 and 0.63–0.95, respectively. At the same OH exposure, SOA on wet AS seeds had both higher O:C ratios and an estimated average carbon oxidation state ($O_{SC}$) ($O_{SC} \approx 2 \times O$; C–H:C) (Kroll et al., 2011) than dry AS seeds had. Figure 6 also shows some of the identified SOA products from the photooxidation of toluene (Bloss et al., 2005; Hamilton et al., 2005; Sato et al., 2007). The elevated $O_{SC}$ (exceeding 0.5) could only be due to the formation of highly oxygenated small acids such as pyruvic acid ($O_{SC} = 0.67$), glycolic acid ($O_{SC} = 1$), formic acid ($O_{SC} = 2$), oxalic acid ($O_{SC} = 3$), malonic acid ($O_{SC} = 1.33$) and glyoxylic acid ($O_{SC} = 2$). Small acids may be important products of toluene-derived SOA at high OH exposures. Fisseha et al. (2004) found that small organic acids accounted for 20–45% of SOA from the photooxidation of 1,3,5-trimethylbenzene. The higher $O_{SC}$ at high OH exposures for wet AS seeds might suggest that these small acids

The change in the slope of $H : C$ vs. $O : C$ is consistent with the earlier analysis that the mechanism of SOA formation changed from functionalization dominated by the addition of alcohol/peroxide (Heald et al., 2010; Ng et al., 2011) at low exposures to the addition of both acid and alcohol/peroxide functional groups without fragmentation, and/or the addition of acid groups with fragmentation at high exposures.

### 3.3 Atmospheric implications

In this work, yields and composition of SOA formed from the photooxidation of toluene on initially wet and dry AS seed particles were compared over a wide range of OH exposures, covering the transition from functionalization reactions to fragmentation reactions. We found that the ratio of SOA yield on wet AS seeds to that on dry AS seeds decreased from 1.31 to 1.01 as the OH exposure increased from $0.47 \times 10^{11}$ to $5.28 \times 10^{11}$ molecules cm$^{-3}$ s$^{-1}$. This decrease coincides with the decrease of differences in ALW between the wet and dry cases, which may be due to water uptake by SOA as well as the early deliquescence of dry AS particles as a result of SOA formation. Hence, the SOA yield and ALW of the initially dry AS seeds approached those of the initially wet AS seeds as OH exposure and ALW increased.

In addition to relatively higher SOA yields, higher $O : C$ and $OS_2$ of SOA derived from the photooxidation of toluene were also observed on initially wet AS seeds. Particularly, the $O : C$ in the presence of initially wet AS seeds could be as high as 0.95. Chen et al. (2015) observed large gaps between laboratory and ambient measured $O : C$ of OA and suggested that OA having a high $O : C$ (> 0.6) was required to bridge these gaps. The multiphase oxidation of toluene in the presence of wet aerosols may be a pathway to contribute to this gap. However, the relative importance of such chemistry to the evolution of ambient OA remains unclear.

Our results suggest that dry seeds would quickly turn to at least partially deliquesced particles upon SOA formation under moderate RH conditions. We only studied the photooxidation of toluene in the absence of NO$_x$ as it is still a challenge to study high-NO chemistry in oxidation flow reactors without using atmospherically irrelevantly high concentrations of NO$_x$ (Peng and Jimenez, 2017). However, the ALW may also be important to SOA formation under high-NO$_x$ conditions that preferentially form highly water-soluble products (Ervens et al., 2011). Since ambient RH is rarely at such low values that inorganic particles remain dry even after SOA formation, more laboratory and field studies are needed to elucidate the formation and evolution of OA under various NO$_x$ conditions at moderate RH.
