Persistent high-risk human papillomavirus (hrHPV) infection is the highest risk to cervical cancer which is the fourth most common cancer in women worldwide. A growing body of literatures demonstrate the role of cervicovaginal microbiome (CVM) in hrHPV susceptibility and clearance, suggesting the promise of CVM-targeted interventions in protecting against or eliminating HPV infection. Nevertheless, the CVM-HPV-host interactions are largely unknown. In this review, we summarize imbalanced CVM in HPV-positive women, with or without cervical diseases, and the progress of exploring CVM resources in HPV clearance. In addition, microbe- and host-microbe interactions in HPV infection and elimination are reviewed to understand the role of CVM in remission of HPV infection. Lastly, the feasibility of CVM-modulated and -derived products in promoting HPV clearance is discussed. Information in this article will provide valuable reference for researchers interested in cervical cancer prevention and therapy.

Keywords: cervical cancer, high-risk HPV, CVM-targeted intervention, CVM-derived product, HPV clearance

INTRODUCTION

Persistent high-risk human papillomavirus (hrHPV) infection is the highest risk to invasive cervical cancer (ICC), which has caused an estimated 570,000 new cases and 311,000 deaths in 2018 (1). Prophylactic vaccines are effective in preventing HPV infection, but providing limited protection against pre-existing HPV infection which impact large populations in developing countries for a long-lasting period (2, 3). It will be an imperative alternative to prevent HPV-infected cervical intraepithelial neoplasia (CIN) and ICC by eliminating HPV infection. An increasing number of literatures suggests the association of natural HPV clearance and CIN regression with cervicovaginal microbiome (CVM) (4–8), which modulate a finely-tuned immune responses balancing reproductive tolerance with protection against genital infections (9). Our and other studies demonstrated predominance of one or few Lactobacillus species in CVM of healthy lower reproductive tract (LRT), including Lactobacillus crispatus (community-state type I, CST I), Lactobacillus gasseri (CST II), Lactobacillus iners (CST III) and Lactobacillus jensenii (CST V) (10–14). These Lactobacillus species benefit reproductive health by inhibiting pathogens via produced bacteriocins, lactic acid and hydrogen peroxide (15).
Emerging reports demonstrate imbalanced CVM in women with HPV infection, including increased bacterial diversity, depletion of Lactobacillus as well as identified high rate of natural HPV clearance in women with predominant L. crispatus in CVM (4, 8, 16–21). To the best of our knowledge, there is no public report investigating the mechanism of interaction between HPV and microbiome, due to difficulties to cultivate HPV in vitro and limited mouse models for HPV-mediated cervical dysplasia or cancer. Nevertheless, a number of studies support the concept that CVM modulates immune microenvironment through microbiota or microbe-host interactions to impact the risk of viral infections and clearance (9, 22–25). For instance, Lactobacillus conferred colonization resistance to Gardnerella vaginalis which induced suppressive immune responses beneficial to persistent HPV infection (22). M N Anahtar et al. demonstrated that CVM was the main modulator of immune responses in lower reproductive tract (LRT) and affected the risk of human immunodeficiency virus (HIV) infection (23). Peptidoglycans (PGN) produced by isolated vaginal L. crispatus activate Langerhans cells (LCs), which is the most important antigen presenting cells (APCs) in cervical epithelium (25), and several follow-up investigations further suggest a strong in vivo relationship between LCs activities and HPV clearance (26–28).

In this review, we first summarize the association of CVM with HPV infection and clearance, then discuss mechanisms of microbiome, host responses and HPV interaction. Lastly, several potentials are explored about how to eliminate pre-existing HPV infection via microbiome-derived products or microbiome-targeted interventions.

**IMBALANCED CVM IN HPV INFECTION**

Emerging evidence suggests association between CVM and HPV infection and persistence. Almost all cross-sectional studies consistently found higher diversity of CVM in HPV-positive women, with or without CIN, as compared to HPV-negative individuals (16–21, 29,32). In recent decade, a growing body of literature suggests that depletion of Lactobacillus and overgrowth of anaerobic bacteria is associated with increased CVM diversity (Figure 1) (16–21, 29, 30). For individuals infected with HPV but without CIN or ICC, initial cross-sectional studies involving Korean (n=68 selected from 912 women in Healthy Twin Study) and Chinese (n=70) women identified reduced levels of Lactobacillus as well as higher abundance of bacterial vaginitis (BV)-associated bacteria such as Gardnerella, Sneathia and Megasphaera (18, 30). This is consistent with increased susceptibility to HPV infection in women with BV revealed by meta-analysis (33). Besides to Gardnerella, Sneathia and Megasphaera, additional reports found greater relative abundance of Atopobium, Bacteroides, Prevotella and lower proportion of Lactobacillus in CVM of HPV-positive women (16, 17, 29). Studies involving women with CIN or ICC consistently found significant decrease of Lactobacillus and substantial increase in CVM diversity compared with HPV-negative individuals (18, 19, 31, 32).

At species level of Lactobacillus, a marked decrease of L. crispatus was found in CVM of women with HPV infection, CIN or ICC, while L. iners-dominant CVM had higher risk of CIN (8, 18, 31, 32, 34). Additionally, women with HPV infection had accumulation of Bacteroides plebeius, Acinetobacter lwofii, Prevotella buccae, Dialister invisus, G. vaginalis, Prevotella buccalis and Prevotella timonensis in CVM (29, 31, 32, 34). For instance, a study involving 70 women with CIN and 50 HPV-negative women indicated that 6-fold risk of CIN associated with unique CVM, which is characterized by paucity of L. crispatus, enriched A. vaginae, G. vaginalis and L. iners (30). Two independent systematic reviews and meta-analysis also found that L. crispatus correlated with decreased risk of hrHPV infection and CIN (35, 36). Compared with L. crispatus-dominant CVM, women with non-Lactobacillus- or L. iners-dominant CVM had 2-3 times higher odds of hrHPV prevalence and CIN, as well as 3-5 times higher odds of any prevalent HPV (95% CI) (35).

Besides to microbial components, emerging literature explores functional difference of CVM between HPV-positive and HPV-negative women (37–39). Functional prediction of 16S rDNA amplicon sequencing data found accumulation of multiple pathways in HPV-infected and CIN women, including those of folate biosynthesis and oxidative phosphorylation (37). Metagenomic analysis of 17 CIN, 12 ICC cases and 18 healthy individuals found enriched genes related to peptidoglycan synthesis as well as depletion of dioxin degradation and 4-oxalocrotonate tautomerase in CVM of women with CIN or ICC (38). Biofilm formation assessment identified higher formation rate in HPV-positive women (45%) compared to HPV-negative women (21.9%) (39), which may be
attributed to increased levels of obligate anaerobic bacteria in CVM of HPV-infected women, such as *G. vaginalis* with sialidase-encoding gene involved in biofilm formation (8).

Above-mentioned observational studies are only possible to demonstrate association of CVM with HPV infection and CIN diseases rather than causality. Longitudinal data is increasingly applied to explore the causal link (7, 40, 41), which has profound clinical impact to provide effective alternatives for therapeutic strategies of HPV-infected CIN. Six-month follow-up of 211 Nigerian women showed the association of *Lactobacillus* paucity and high CVM diversity with persistent hrHPV infection (40). Analysis of serial cervicovaginal specimens obtained over 8-10 years unraveled that high relative abundance of *L. crispatus* in CVM had the lowest risk of HPV infection compared to other types of CVM, according to 16S V1-V2 rRNA gene amplicon sequencing and HPV DNA testing conducted annually (41). Brotman and colleagues collected self-sampled mid-vaginal swabs twice a week for 16 weeks from 32 reproductive-age women, and showed that depletion of *Lactobacillus* in CVM may increase the chance to acquire transient and persistent HPV infection (7). Consistently, meta-analysis involving 39 articles suggests the protection against HPV infection imposed by *Lactobacillus*-dominant CVM (42). Another systematic review and meta-analysis of longitudinal studies also support a causal relationship between non-*Lactobacillus*-dominant CVM and cervical carcinogenesis via the effect of CVM on HPV infection (RR 1.33, 95% CI) and persistence (RR 1.14) (43).

**CVM IS ASSOCIATED WITH NATURAL HPV CLEARANCE AND CIN REGRESSION**

According to a follow-up analysis on 55 women with HPV infection and 17 age-matched healthy HPV-negative women, *L. crispatus* was the most abundant *Lactobacillus* species in individuals with natural HPV clearance (Figure 2A) (8). Conversely, high proportion of *Atopobium* in CVM had significantly slowed HPV remission rate in 16-week follow-up, compared to *L. crispatus*-dominant CVM (43). Another longitudinal study involving 64 HPV16-positive women found more frequent transition between identified CSTs, including dominant *Lactobacillus* sp., *L. iners*, two mixed non-*Lactobacillus* of CVM, in women with persistent HPV16 infection (34% with averaged 155.5 days interval) when compared to women with natural clearance of HPV16 (19% with averaged 162 days interval) (Figure 2A) (6). Consistently, Anita Mitra and partners found more stable CVM in women with CIN2 regression, as compared to individuals with CIN persistence or progression (4). In this study,
87 CIN2 patients aged 16-26 years old were included in two-year follow-up showing that women with *Lactobacillus*-dominant CVM at baseline are more likely to regress at 12 months while slower regression was associated with *Lactobacillus* depletion as well as increased abundance of *Megasphaera*, *Prevotella timonensis* and *G. vaginalis* (4). At species level, women with *L. crispatus*-dominant CVM had faster regression and higher rate of CIN remission at 12 and 24 months (4).

A total of four CSTs, dominated by *L. crispatus*, *L. iners*, *G. vaginalis* and mixed genus, was identified in another study involving 273 women aged 18-25 years old (5). At first visit, *Lactobacillus* and *Gardnerella* abundance was associated with CIN2 regression and progression respectively. Second visit was conducted at least 305 days after first visit, and CIN2 progression had strong correlation with increased bacterial diversity. Functional prediction of 16S rDNA amplicon sequencing data further showed the positive relationship between pathway of cell motility and CIN2 regression, while progression was in association with “Xenobiotics Biodegradation and Metabolism” pathway in CVM.

Fungal components in CVM were also associated with HPV-infected CIN regression (5). Mykhaylo Usysky and colleagues found the protective effect of fungal diversity against CIN progression (OR=0.90, 0.82-1.00) (5). Among fungus *Candida*, *Malassezia* and *Sporidiobolaceae*, the accumulation of *Candida* was identified in CVM of CIN1 which had the highest regression rate (5). Additionally, a retrospective investigation on 100,605 women who had 2 smears each over a period of 12 years, found that common fungus *Candida* in cervicovaginal microenvironment decreased the risk of squamous intraepithelial lesions (44).

**MICROBE- AND HOST-MICROBE INTERACTIONS IN HPV CLEARANCE**

The complexity of cervicovaginal microenvironment of women with HPV infection is determined by HPV, CVM and the host. To explore the contribution of CVM to promote or protect against HPV infection, there is much work to be done in exploring microbe-microbe interactions in CVM, as well as the interactions between microbe and HPV/host (Figure 2B).

Sialidase are a group of mucin-degrading enzymes produced by BV-associated *G. vaginalis* and *Prevotella*, and disrupt the integrity of mucosa as well as epithelium to aid the entry of HPV to basal keratinocytes (Figure 2A) (45). Besides to compromised cervical epithelial barrier, BV-associated anaerobes also impact several cellular pathways to enable persistent viral infection and subsequent disease development (46–50). *Sneathia* spp., commonly accumulated in CVM of BV and HPV-infected patients, belongs to *Fusobacterium* genus which can activate proinflammatory pathways and inhibit immunocytotoxicity to promote carcinogenesis (51). This information may explain the high susceptibility to HPV infection in women with BV and accumulation of vaginal obligate anaerobic bacteria in women with persistent HPV infection or cervical dysplasia progression (16–18, 29, 30, 33).

Vaginal *Lactobacillus* spp. can produce a large amount of lactic acid through glycolyen fermentation, maintaining acidic environment to inhibit the colonization of several pathogenic species such as *Chlamydia trachomatis*, *Neisseria gonorrhoeae* and BV-associated *G. vaginalis* (Figure 2B) (15, 52–55). Bacteriocins produced by vaginal *Lactobacillus* also exhibit inhibitory effects on common pathogenic bacteria and certain fungi, such as *G. vaginalis* and *Candida albicans* (Figure 2B) (15, 56, 57). In addition, *Lactobacillus* hold the potential to alter surface tension and thus bacterial adhesion which is pivotal in biofilm formation via excreted biosurfactants, therefore preventing overgrowth of pathogenic anaerobes, especially *G. vaginalis* (Figure 2B) (22, 58–60). Another defense factor derives from vaginal *Lactobacillus* is H2O2, which destroys vaginal bacterial components with limited expression of H2O2-degrading enzymes, including *Prevotella* and *Gardnerella* (60, 61). Besides direct inhibition on pathogens, *Lactobacillus* can occupy possible niches to indirectly protect against pathogen colonization (Figure 2B). For instance, epithelium adhesion facilitates the adhesion of *L. crispatus* to genital mucosa and then additionally inhibits pilus-mediated adhesion of *G. vaginalis* (22).

As discussed above, vaginal *Lactobacillus* play critical roles in cervicovaginal health, but not all *Lactobacillus*-dominant CVM benefit the host in the same manner. Lactic acid has D- and L-isomer while the former is mainly produced by *L. jensenii*, *L. crispatus*, *L. gasseri* and the latter is produced by *L. iners* and a variety of anaerobes (62). Women with *L. iners* or non-*Lactobacillus*-dominant CVM therefore have a higher ratio of L- and D-lactate, increasing the expression of extracellular matrix metalloproteinase inducer and activating extracellular matrix metalloproteinase 8, which facilitate the entry of HPV to the basal keratinocytes by altering cervical integrity (Figure 2A) (62). Conversely, *L. crispatus*-dominant CVM can lead to increased cervicovaginal mucus viscosity and promote viral capture (63). Additionally, CVM predominated by *L. iners* is more instable than CVM with other dominant *Lactobacillus* species and therefore allows growth of strict anaerobes resulting in transition to non-*Lactobacillus*-dominant CVM (4, 64). This is consistent with findings that *L. iners*-dominant CVM tends to be identified in women with persistent HPV infection and progression of cervical diseases (Figure 2A) (8, 18, 31, 32, 34). On the contrary, *L. crispatus*-dominant CVM has the lowest possibility in transition to other CVM types (4, 13, 64), and is thus positively associated with cervicovaginal health (Figure 2A).

Though many clues exist in microbe-microbe interactions, there are no published reports exploring the mechanism of interaction between CVM and HPV, due to the difficulties of *in vitro* HPV cultivation. Nevertheless, a growing number of literatures demonstrate unique host immune responses (Figure 2B) (65), which mediate the CVM-HPV interactions in women with HPV infection. Oncoproteins of hrHPV can suppress presentation of hrHPV antigens and impair alarm functions of infected basal keratinocytes where HPV thrive. For example, hrHPV E7 protein can lead to repression of major histocompatibility complex I (MHC I), LMP2 as well as...
APPLICATION OF CVM IN PROMOTING HPV CLEARANCE

Given the critical roles of CVM in modulating cervical immune responses, it is promising to promote HPV clearance by reconstituting CVM (Figure 3A). Taken vaginal probiotics *L. crispatus* strain CTV-05 for example, a randomized placebo-controlled clinical trial showed that the vaginal colonization with CTV-05 following 28-day treatment inhibited BV-associated *Atopobium* growth (89, 90). Another trial involving 100 participants assessed the efficacy of CTV-05 on preventing urinary tract infection (UTI), indicating the reduction of recurrent UTI when compared to placebo treatment (91). Disrupting biofilm of anaerobes is also an alternative therapy against vaginal dysbiosis, and Marrozzo J. M. et al. found 50-59% clinical cure rate of BV in 106 participants 9-12 days after treatment (92).

In addition, several *in vitro* and *in vivo* studies suggest the promise of prebiotics, which are indigestible carbohydrates, in promoting the growth of probiotics or beneficial commensals in the vagina (Figure 3A) (93–95). For example, fructooligosaccharide (FOS) and gluco-oligosaccharide (GOS) benefited the growth of *L. crispatus, L. jensenii* and *L. vaginalis in vitro*, while pathogen *C. albicans, Escherichia coli* and *G. vaginalis* could not utilize FOS/GOS as energy sources for growth (93). Significant reduction of Nugent scores was also identified in BV patients receiving intravaginal GOS gel immediately following metronidazole treatment (94). Additionally, glucosmannan hydrolases (GMH) also held the potential to promote *Lactobacillus* spp. colonization, conferring health to the host in *C. albicans*-infected women (95). To re-establish the CVM completely, two studies in 2019 conducted vaginal microbiota transplantation (VMT) (Figure 3A) (96, 97). A total of 5 women with antibiotic-unresponsive and recurrent BV were included in one study, and 4 out of 5 participants had restoration of *Lactobacillus*-dominant CVM and long-term remission without any adverse effect at the follow-up of 5-21 months. The other study involving 20 women explained and implemented a screening approach for universal VMT donors.

Besides to CVM-targeted interventions, CVM-derived products hold the promise as immune modulators, such as adjuvants of therapeutic vaccines (Figure 3B). Jie Song and co-workers demonstrated that PGN produced by a vaginal *L. crispatus* strain enhanced the expression of cell-membrane TLR2 and TLR6 to activate LCs (25), which play a pivotal role in capturing and presenting HPV antigens. The products of specific bacterial components have the potential to be effective adjuvants as a series of clinical trials demonstrated enhanced efficacy of therapeutic vaccines adjuvanted with TLR agonists which could be served by *Candida* which partly explain the protection of vaginal *Candida* against HPV infection (44, 83, 84).

CONCLUSION

CVM appears to play a crucial role in HPV acquisition and persistence as well as subsequent development of squamous
intraepithelial lesion. Cross-sectional nature of most studies makes it difficult to derive a causal link between CVM and HPV infection or clearance. In addition, many prior reports described CVM in relatively small cohorts, which analysis results could be compounded by various factors, such as smoking and sex activities. Prospective cohort study will be needed in the future to prove that CVM could prevent HPV infection and promote HPV clearance. This information will determine the promise of CVM interventions as novel therapies, with the advantage of low-cost feasibility in developing countries. Nevertheless, it is imperative to find the most protective strains before developing CVM-targeted probiotics or prebiotics, for which the efficacy can be impacted by pre-existing CVM. For example, *L. crispatus*-dominated CVM confers high colonization resistance to other microbes and even probiotic *L. crispatus* strain, while pre-colonization of the vagina with endogenous *L. iners* allows growth of anaerobes. Therefore, CVM structure should be taken into consideration when it comes to assess the efficacy of specific probiotics and prebiotics. However, 16S rDNA amplicon sequencing that most studies applied has limitations in conducting strain-level analysis and microbiome/microbe/host interactions of CVM, necessitating the utilization of multi-omics in analyzing “key microbial strains”. Then mechanistic studies of these strains should be conducted to further the utilization of “key microbial strains” as immune modulators in prevention and clearance of HPV infection. Given the importance of cervical epithelial LCs in presenting HPV antigens to induce HPV-specific CMI, it will be an effective mediator of therapeutic vaccine immunity. As discussed above, specific microbial strains in CVM hold the potential to activate HPV-suppressed LCs, suggesting the promise of microbial products as robust activator of immunity against HPV or adjuvants in therapeutic vaccines. In the future, the combination of culture-independent and -dependent techniques should be applied to screen promising microbial strains and products which functions can be assessed in cell lines or animal models. Lastly, though VMT can modify the whole cervicovaginal microenvironment, randomized, placebo-controlled studies for large cohorts are required to determine the clinical efficacy as well as long-term benefits.

**FIGURE 3** | CVM-modulated and -derived products in eliminating HPV infection. (A) Strategies to modulate dysbiotic CVM were characterized by anaerobe overgrowth. (B) Molecules produced by specific microbial strains in CVM can activate LCs in the cervical epithelium, then promote T cell priming and eliminate HPV-infected cells.
